NATURE

A WEEKLY

ILLUSTRATED JOURNAL OF SCIENCE

VOLUME XXV.

NOVEMBER 1881 to APRIL 1882

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH

London and New York:
MACMILLAN AND CO.
1882

LONDON:
R. CLAY, SONS, AND TAYLOR, PRINTERS,
BREAD STREET HILL, E.C.

INDEX

ABBOTT (Chas. C.), "Primitive Industry, or Illustrations of the Handiwork in Stone, Bone, and Clay, of the Native Races of the Northern Atlantic Seaboard of America," 27
Abel and Roscoe's (Profs.), Reception at the Crystal Palace, 491
Aberdeen, Sir Erasmus Wilson's Chair of Pathological Anatomy at, 301
Abney (Capt., F.R.S.), Solar Physics, 162, 187, 252
Absolute Sine Electrometer, Geo. M. Minchin, 290
"Abyssinia," Father Lobo's, 365
Accidents in Mines Commission, 97
Accumulators, Planté and Faure, Chemistry of the, Dr. J. H. Gladstone, F.R.S., and Alfred Tribe, 221, 461
Acetylene, the Spectrum of, 290
Acoustics, Light and Heat, Thomas W. Piper, 51
Actinium, a New Metal, 394
Adams (Prof. W. Grylls, F.R.S.), Magnetic Disturbances, Auroras, and Earth Currents, 66
Africa: Dr. Stecker's Exploration of Lake Tana, 209; Reimer's "Beiträge zur Entdeckungsgeschichte Afrika's, 232; Ravenstein's New Map of East Central, 250; Relief Map of the Equatorial Region of, 275; German Exploration of, 302; Dr. Max Buchner's exploration of the Lunda District, 395
Agram, Earthquake at, 63, 186, 326
Ainos, Bear Festival among the, 345
Air, Essays on the Floating Matter of the, in Relation to Putrefaction and Infection, John Tyndall, F.R.S., 6
Algæ, British Freshwater, Dr. M. C. Cooke's Work on, 565
Algæ and Animals, Symbiosis of, 377
Algebra, E. J. Gross, 458
Algerian System of Meteorological Observations, 492
Alglave (Em.), and J. Boulard, "La Lumière Electrique son Histoire, sa Production, et son Emploi," 359
Algol Type, Variable of the, 186
Allen (Chas. H.), Parhelia in the Mediterranean, 339
Allen (Grant), "Vignettes from Nature," 381, 435, 459, 480, 554
Alps, Prof. Civiale's work on the, 519
Amazons and Andes, between the, or Ten Years of a Lady's Travels in the Pampas, Gran Chaco, Paraguay and Matto Grosso, Mrs. M. G. Mulhall, 457
America: "American Naturalist," 47, 210, 426; "American Journal of Science," 257; American Association for the Advancement of Science, 324; "The Honey Ants of the Garden of the Gods, and the Occident Ants of the American Plains," Dr. Henry C. McCook, G. J, Romanes, F.R.S., 405
Amorphophallus Titanum, 206
Ancient Monuments, Preservation of, 393
Andaman Islands, Earthquake in the, Col. H. H. Godwin-Austen, 386
Andromeda, the Great Nebula in, Rev. T. W. Webb, 341
Anemometers: Integrating, V. Ventosa, 79; Proposed Exhibition of, 249, 450; J. K. Laughton on, 547
Animals: Illustrations of New or Rare, in the Zoological Society's Living Collection, 295, 391, 608
Animals Containing Chlorophyll, Researches on, Patrick Geddes, 303, 361; Prof. H. N. Moseley, F.R.S., 338; Dr. E. Percival Wright, 361
Animals, Symbiosis of Algæ and, 377
Animals, on the Sense of Colour among some of the Lower Animals, Sir J. Lubbock Bart., F.R.S., 422
Animals, Aristotle on the Parts of, translated by W. Ogle, Dr. B. W. Richardson, F.R.S., 453 505
Annalen der Physik und Chemie, 142, 282, 401, 522
Ant Trap, Natural, J. Harris Stone, 151
Antarctic Expeditions, 473, 613
Anthropological Institute, 71, 143, 235, 355, 380, 451, 475, 499, 571, 619
Antiseptic, New, Prof. Barff's, 535
Anti-vivisection, *versus* Humanity, 73
Antlers in the Ruminants, Evolution of, Prof. W. Boyd Dawkins, F.R.S,, 84
Ants, Sound-producing, H. F. Blanford, 32; J. Fotheringham, 55; D. M. Lewis, 266
Apiculture, International Exhibition of, 493
"Appalachia," 493
Apus, Limulus and Scorpio, Studies on, Prof. E. Ray Lankester, F.R.S., 479
Archæological Discovery at Angleur, near to Liége, 419
Archer (F.), Replacing Flint Flakes, 8
Archibald (E. Douglas), Variations in the Sun's Heat, 316; Conservation of Solar Energy, 504
Architects, Institution of Naval, 533
Archives des Sciences Physiques et Naturelles, 257, 401, 522, 618
Arctic Research: Dr. J. Rae, F.R.S., 53, 102; Clements R. Markham, C.B., F.R.S., 78; D. Wetterham, 102; General Hazen on, 112; the Search for the *Jeannette*, 44, 62, 89, 275, 326, 350, 375; the *Eira* Expedition, 123, 209; the Season of 1881, 136; International Polar Research, 113; Ice Fields in the Arctic Regions, 536; an Arctic Night at the Geographical Society, 159; Arctic Success and Disaster, 169
Arendts (Dr. Carl), Death of, 63
Argentine Republic, Cameos from the Silver Land; or, the Experiences of a Young Naturalist in the, E. W. White, 480
Argyll (Duke of, F.R.S.), Struggle of Parts in the Organism, 6
Aristotle on the Parts of Animals translated by W. Ogle, Dr. Benjamin Ward Richardson, F.R.S., 453, 505
Aristotle on the Heart, W. Ogle, 528
Aristology; or, the Art of Dining, Thos. Walker, 478
Aroid, a Gigantic, 206
Arosenius (Herr J. N.) on the Ethnographical Frontier between Finns and Swedes in Northern Sweden, 113
Artificial Deformation of the Human Skull in the Malay Archipelago, Dr. A. B. Meyer, 132
Asbestos Paint, Experiments with, at the Crystal Palace, 276
Asia, Central, Dr. Regel's Journey in, 349
Askabad and Sarakhs, Levelling of the Country between, 421
"Astral Origin of the Emblems and Hebrew Alphabet," J. H. Broome, Prof. A. H. Sayce, 525
Astronomy: Astronomical Column, 19, 43, 94, 114, 126, 186, 209, 218, 278, 326, 349, 375, 421, 450, 471, 493, 519, 538, 566, 593, 616; Webb's Celestial Objects for Common Telescopes, 98; Observatory added to the University of St. Petersburg, 230; Astronomical Observations, on the Climate of North Northumberland as regards its fitness for, Rev. Jevon J. Muschamp Perry, 317, 364; J. Lingwood, 339; New Astronomical Magazine; "Les Etoiles et les Curiosités du Ciel," C. Flammarion, 456; "Populäre Astronomie von Sim. Newcomb, Astronom in Washington," Dr. Phil, 456
Atacama, Climate of, Hyde Clarke, 9
Atkinson (A. S.), Telescopic Definition in a Hazy Sky, 483
Atlantic, Chemistry of the, J. Y. Buchanan, 387, 411
Atlas of Universal Geography, Stanford's London, 383
Atmosphere, Movements of Jupiter's, W. Mattieu Williams, 338; G. H. Darwin, F.R.S., 360
Atmospheric Phenomenon, J. B. Hannay, 125
Atomic Weights, Prof. F. W. Clarke's Recalculations of, 537
Atti della R. Accademia dei Lincei, 305, 353, 545
Attitudes retained by Soldiers who have Died on the Battlefield, 230
Audible Photometer, J. W. Giltay, 125
Aurora, the, 319, 368
Auroras, Earth Currents, and Magnetic Disturbances, Prof. W. Grylls Adams, F.R.S., 66
Aurora and its Spectrum, J. Rand Capron, 53
Auroral Display, Thos. Gwyn Elger, 386; W. G. Koch, 461
Australia, Water in, F. T. Mott, 507; Sparrows in South, 18
Autumn Sky, Rev. T. W. Webb, 9, 36
Aveling (Edward B.), Natural Philosophy for London University Matriculation, 76
Awned Carpels of Erodium, Prof. G. Macloskie, 174
Axon (W. E. A.), Pronunciation of Deaf-Mutes who have been Taught to Articulate, 101, 409
Ayrton (Prof. W. E., F.R.S.), on the Economical Use of Gas-Engines for the Production of Electricity, 280; Storage of Energy, 495

Baboon, Pet, Julia Wedgwood, 217
Badcock (J., jun.), Red Flints in the Chalk, 529
Baildon (Sam.), "Tea Industry in India; a Review of Finance and Labour, and a Guide for Capitalists and Assistants," 551
Balfour's (F. M., F.R.S.), Treatise on Comparative Embryology, Prof. E. Ray Lankester, F.R.S., 25
Ball (Prof. Robert S., F.R.S.), a Glimpse through the Corridors of Time, 79, 103
Balloons: Accident to W. Powell, M.P., 159, 185, 208; Rime Cloud observed in a Balloon, W. de Fonvielle, 337, 436, 529; Dr. Hermann Kopp, 385, 507; Proposed Balloon Journey across the Channel, 373; Balloon Ascent from La Villette Gasworks, Paris, 373; Col. Brine and Mr. Simmons' Expedition, 449; Col. Burnaby's Trip across the Channel, 518
Barff's (Prof.) New Antiseptic, 535
Barnard (E. E.), Meteors, 173
Barometer, New, Marshall Delaey, 290; Simple Registering, 374; Electric Barometer, J. Joly, 559
Barrett (Prof. W. F.), Antoine Breguet's Appropriations, 364
Basque Provinces of Spain, on the Whale Fishery of the, Clements B. Markham, F.R.S., 365
Basque Whale in the Mediterranean, Prof. Henry Hillyer Giglioli, 505
Bast Fibre, Chemistry of, C. F. Cross and E. J. Bevan, 351
Bastian (Adolf.), "Die heilige Sage der Polynesier-Kosmogonie und Theogonie," Edward B. Tylor, F.R.S., 28; "Der Völkergedanke in Aufbau einer Wissenschaft vom Menschen, und seine Begründung auf ethnologische Sammlungen, 77; "Die Vorgeschichte der Ethnologie," 77
Batoum, Shock of Earthquake at, 250
Batrachia, Salientia, and Ecaudata in the Collection of the British Museum, Catalogue of the, G. A. Boulenger, 601
Battery, New Electrical Storage, Henry Sutton, 198
Bauerman (Hilary), "Text-Book of Systematic Mineralogy," L. Fletcher, 49
Bavaria, Earthquakes in, 375
Bear Festival among the Ainos, 345
Bees, Dangers arising from, 420
Bela Lime Alps, Cave discovered in, 89
Belgium, Astronomy in, 537
Bell (Alex. Melville), Sounds and their relations, 503
Bell (F. Jeffrey), Teaching of Practical Biology, 8
Bell (Prof. Graham), Probing by Electricity, 40; Pronunciation of Deaf-Mutes who have been taught to articulate, 124, 458
Ben Nevis, Meteorology of, Alex. Buchan, 11; the Meteorological Observatory on, 135; Clement L. Wragge's Meteorological Observations on, 491; Ascent of, 372
Berlin: Geographical Society, 44; Zeitschrift of, 538; Banquet in Honour of Prof. Virchow at, 62, 87; Aëronautical Society founded at, 89; Philosophical Society of, 114; African Society of, 302; Society of Commercial Geography, 492; Physiological Society, 620
Beryl and Tourmaline, Specimens of, at the Florence Institute, 373
Bevan (E. J.) and C. F. Cross, Chemistry of Bast Fibre, 351
"Bilderschriften des Ostindischen Archipels und der Südsee," 17
Bilek, Earthquake at, 537
Billet (M. Felix), Death of, 395
Binary Stars, 421; γ Virginis, 19; η Cassiopeiæ, 186
Binney Edward William, F.R.S.), Obituary Notice of Dr. J. P. Joule, F.R.S., 293
Biology: Teaching of Practical, F. Jeffrey Bell, 8; Biology in Schools, Geo. W. Peckham, 151; Biological Notes, 327; "Biologische Probleme, zugleich als Versuch einer rationellen Ethik," W. H. Rolph, 336
Birds: Jurassic, and their Allies, Prof. O. C. Marsh, 22; Dr. R. W. Schufeldt on the Osteology of, 136; New Birds from the Solomon Islands, 282; Intelligence in Birds, 410; Mrs. E. Hubbard, 461
Birmingham (J.), New Red Star in Cygnus, 198, 484
Birt (W. R.), Death of, 219
Bischoffsheim Observatory, 199
Bivalves, on the Dispersal of Freshwater, Chas. Darwin, F.R.S., 529; D. Pidgeon, 584; Frank J. Rowbotham, 605
Bjerknes' Hydrodynamic Experiments, 271
Black Bass, Book of the, Dr. J. A. Henshall, 216
Blackley (Chas. H.), Heads and Hats, 55
Blanford (H. F.), Sound-producing Ants, 32
Bloxam (Prof.) and the Royal Military Academy, 591
Blum (R.), Current Meter, Prof. Harlacher, 494
Bock (Carl), "Head-Hunters of Borneo: a Narrative of Travel up the Mahakkam and down the Barito, also Journeyings in Sumatra," Alfred R. Wallace, 3
Bokorny (Thos.) and Oscar Loew, "Chemical Cause of Life Theoretically and Experimentally Examined," 457
Bolometer, the, 14
Bonney (Rev. T. G.) Silurian Fossils in the North-West Highlands, 603
Borneo, Head-Hunters of: a Narrative of Travel up the Mahakkam and down the Barito, also Journeyings in Sumatra, Carl Bock, Alfred R. Wallace, 3
Boston, U.S.A., American Academy of Arts and Sciences, 260, 523; Society of Natural History, 1830-1880, 389
Boston Church, Meteorological Observations made on, 470
Boué (Ami), Obituary Notice of, by Prof. A. Geikie, F.R.S., 109
Bouillaud (Dr.), Death of, 42
Boulard (J.), and Em. Alglave "La Lumière Electrique son Histoire sa Production et Son Emploi," 359
Boulenger (G. A.), Catalogue of the Batrachia, Salientra and Ecaudata in the Collection of the British Museum, 601
Bowman (W., F.R.S.), elected Honorary Secretary to the Royal Institution, 346
Brady (Sir Antonio), Obituary Notice of, Dr. Henry Woodward, F.R.S., 174
Bramsen (William), Death of, 160
Breguet's (M. Antoine) Appropriations, Prof. W. Barrett, 364
Bress (Dr. A.), Abriss der Zoologie für Studirende Ärzte und Lehrer, 337
Brewster (Sir David), his Scientific Work, 157
Bridges, Tay and the Forth, 246
Brighton Health Congress, and Domestic and Scientific Exhibition, 18, 161, 175
Bristol Naturalists' Society, Proceedings, 208
British Association, Meeting for 1882, 324
British Museum, Fossil Fishes at the, 418
Brittany, disappearance of the Sardine from the Coast of, 493
Broome (J. H.), "Astral Origin of the Emblems and Hebrew Alphabet," Prof. A. H. Sayce, 525
Brown (Robert, Jun.), the Unicorn and Mythological Investigation, Prof. A. H. Sayce, 525
Brownell (J. T.), Solar Halo, 290
Bubbles, Phenomena of the Bursting of, M. Plateau on, 160
Buchan (Alex.), Meteorology of Ben Nevis, 11
Buchanan (J. Y.), Chemistry of the Atlantic, 387, 411
Budden (W.), Vignettes from Nature, 529
Buenos Ayres, Continental Exhibition at, 591
"Bugs, Overflow," in California, C. V. Riley, 386
Bulletin de l'Academie Royale des Sciences de Belgique, 48, 257, 545, 617
Bulletins de la Société d'Anthropologie de Paris, 545
Bulletin de la Société Impériale des Naturalists de Moscou, 571
Bulletin of the Terry Botanical Club, 571
Burg (Adam von), Death of, 372
Burnaby (Col.), Balloon Trip across the Channel, 518
Burrowing Larvæ, V. T. Chambers, 529
Bussy (M. Antoine Alexander Brutus), Death of, 395
"Butterflies: their Structure, Changes, and Life Histories, with Special Reference to American Forms," being an application of the "Doctrine of Descent" to the Study of Butterflies, Sam. H. Scudder, 5

Cable, the Dover and Calais, 206
Cœsium, the Isolation of, 419
California, "Overflow Bugs" in, C. V. Riley, 386
Callaway (C.), Hypothetical High Tides, 385, 436
Caltanisetta, Sicily, Series of Caverns Discovered at, 250
Cambridge, the New Professorship of Morphology, 543
Cameos from the Silver Land: or, the Experiences of a Young Naturalist in the Argentine Republic, E. W. White, 480
Cameron (Donald), a Strange Phenomenon, 437
Canada, Proposed Academy for, 326
Capron (J. Rand), Aurora and its Spectrum, 53; Solar Gas-flame and Electric Light Spectra, 152; Temporary Retinal Effects, 507
Carbon, Electrical Resistance of, under Pressure, H. Tomlinson, 459; Prof. Silvanus P. Thompson, 482
Carbon, on the Spectrum of, Prof. Liveing and Dewar, 545
Carbonate of Ammonia, Action of, on the Roots of Certain Plants, and on Chlorophyll Bodies, Chas. Darwin, F.R.S., 489
Carnac, Excavations at, James Miln, 99

Carpels, Awned, of Erodium, Prof. G. Macloskie, 174
Carpenter (Dr. William B., F.R.S.), Struggle of Parts in the Organism, 6, 52, Vignettes from Nature, 435, 480, 554, the Microscope and its Revelations, 502
Cassell's Popular Natural History, Edited by P. Martin Duncan, F.R.S., 107
Cassiopeiæ, Binary Star η, 186
Castelfrentano, Earthquake at, 420
Cat, the, St. George Mivart, F.R.S., 286
"Catalytic Action," so-called, 567
Caucasus, the Geology of, 277
Cave discovered in the Bela Lime Alps, 89
Cecil (Henry), Meteor, 78
"Celestial Objects for Common Telescopes," Rev. T. W. Webb, 98
Cell, on an Experimental Form of Secondary, Prof. A. S. Herschel, 363, 527
Centaurea jacea, Polymorphism of the Flower Heads of, Dr. Hermann Müller, 241
Central Asia, Dr. Regel's Journey in, 349
Ceraski's Variable Star U Cephei, 493
Cerebral Localisation, Prof. Sigmund Exner, Dr. David Ferrier, 214
Cerium Metals, New Compounds of, 568
Ceylon, the Lepidoptera of, Henry Trimen, 32, 338; F. Moore, 79; the New Ceylon, 315
Chalk, Red Flints in the, W. Fream, 437; J. Badcock, jun., 437
Challenger, Echinoids of the, Prof. H. W. Mackintosh, 41; Pressure Errors of the *Challenger* Thermometers, Prof. P. G. Tait, 90, 127
Chambers (V. T.), Burrowing Larvæ, 529
Channel Tunnel, A. Strahan, 463; Tele-dynamics and the Accumulation of Energy—their Application to the, E. Walker, 152
Charts, Daily Weather, in the North Atlantic, 605
Chemistry: an Error in the commonly-accepted Theory of, Prof. A. W. Williamson, F.R.S., 21; Chemical Society, 48, 95, 167, 192, 331, 379, 427, 474, 546, 547, 595, 619; "A Treatise on Chemistry," H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., H. Watts, F.R.S., 50; Student's Handbook of Chemistry, H. Leicester Greville, 123; Inorganic Chemistry, Theoretical and Practical, W. Jago, 150, 364; Practical Chemistry, J. Howard, 150; Chemistry of the Planté and Faure Accumulators, Dr. J. H. Gladstone, F.R.S., and Alfred Tribe, 221, 461; Annals of Chemical Medicine, Dr. J. L. W. Thudicum's 263; Chemistry of Bast Fibre, C. F. Cross and E. J. Bevan, 351; Chemistry of the Atlantic, J. Y. Buchanan, 387, 411; "Chemical Cause of Life Theoretically and Experimentally Examined," Oscar Loew and Thos. Bokorny, 457; Chemical Notes, 567; "Chemical Repulsions," 567
Chesterfield, Electric Light at, 42
Chieti, Earthquake at, 420
China: Telegraph in, 88; Competitive Examinations in, 160; Medical Women in, 206; Experiments in the Culture of Chinese Soja Bean, 250; Earthquakes in, 325; Gray's Anatomy translated into Chinese, 394; Scientific Lectures in Chinese at the Schools in Peking, 449; E. C. Baber's Travels and Researches in Western, 472; Railways in, 493; a System of Meteorological Observations in the China Seas, 368; Dr. A. Woeikof, 410; Chinese Burial in Former Times, 518; Dr. Bretschneider on Chinese Botany, 614
Chios, Earthquake at, 492
Chisholm (G. G.), the Two Hemispheres: a Popular Account of the Countries and Peoples of the World, 337
Chlorophyll, Researches on Animals containing, Patrick Geddes, 303, 361; Prof. H. N. Moseley, F.R.S., 338; Dr. E. Perceval Wright, 361
Chlorophyll Bodies, Action of Carbonate of Ammonia on the Roots of certain Plants and on, Chas. Darwin, F.R.S., 489
Christie (W. H. M., F.R.S.), Sun-Spots, 337
Christison (Sir Robert), Death of, 324; Obituary Notice of, 339
Chrystal (Prof. G.), Treatise on Electricity and Magnetism, 237
"Cinchona," 420
City and Guilds of London Institute, Distribution of Prizes and Certificates in the Schools connected with, 161
Clark (J. Edmund), Phenological Observations on Early Flowers and Winter Temperatures, 552
Clarke (Hyde), Climate of Atacama, 9; Alleged Diminution in the Size of Men's Heads, 32
Clenching of Hands from Emotional and other Causes in the two Sexes, on the, Arthur Stradling, 364
Climate of Atacama, Hyde Clarke, 9
Climate of North Northumberland as regards its Fitness for Astronomical Observations, Rev. Jevon J. Muschamp Perry, 317, 364; J. Lingwood, 339
Climate, Glaciers and Glacial Periods in their Relation to, Dr. A. Woeikof, 424
Cloud, Rime, observed in a Balloon, W. de Fonvielle, 337, 436, 529; Dr. Hermann Kopp, 385, 507
Coal-Seams, Possibility of finding, workable under the London Area, Prof. J. W. Judd, F.R.S., 311, 361
Cobbe (Miss Frances Power), and Vivisection, H. H. Johnston, 459; Muffs and Vivisection, 483
Cohn (Dr. Ferdinand), "Die Pflanze. Vorträge aus dem Gebiete der Botanik," W. Botting Hemsley, 359
Coins, Old, Transformation of, in a Lake, 93
Coins of the Jews, International Numismatic Orientalia, Fred. W. Madden; Dr. John Evans, F.R.S., 549
Cole (Sir Henry), Death of, 590; Obituary Notice of, 611
Collet (A.), "Traité Théoretique et Pratique de la Régulation et de la Compensation des Compas, 382
Collieries, Dust-Explosions in, Prof. T. E. Thorpe, F.R.S., 488
Colliery Explosions, Means of Saving some Lives in, D. Rhys Jones, 508
Colorado River, Excavations of the Grand Cañons, 565
Colour, Experiments on, Lord Rayleigh, F.R.S., 64
Colour and Sound, Karl Pearson, 339
Colour, on the sense of, among some of the Lower Animals, Sir J. Lubbock, Bart., F.R.S., 422
Colours of Flowers, Seasonal Order in, Dr. J. C. Costerus, 481
Colours of Low-growing Wood Flowers, J. Innes Rogers, 554
Colour Perception, J. B. Hannay, F.R.S., 604
Colour-Disks, on Combining, Char. K. Wead, 266
Coltsfoot, T. S. Maskelyne, 290
Comets: Comet 1881 *f* (Denning), 19, 126, 413; Great Comet of 1861, 94; Photograph of Comet B, 1881, 132, 218; the Great Comet of 1881, 278, 349, 519; a New Comet, 126, 521; Comets of Short Period, 209; Comet 1882 *a*, 538, 593; Systematic Search for Comets, 566; the Present Comet, 616
Comparative Embryology, Treatise on, F. M. Balfour's, F.R.S., Prof. E. Ray Lankester, F.R.S., 25
Compass, "Traité Théorique et Pratique de la Régulation et de la Compensation des Compas," A Collet, 382
Compressed Air upon Tramways, W. D. Scott Moncrieff, 266
Comstock Lode, Temperatures of the Ground in, 592
Conductivity, Thermal, Specific Heat and, H. G. Madan, 507
Coniferæ, Chapter in the History of, the Podocarpeæ, J. Starkie Gardner, 228
Conservation of Solar Energy, Dr. C. W. Siemens, F.R.S., 440, 504, 603; E. Douglas Archibald, 504; Prof. Chas. Morris, 601; Dr. J. Sterry Hunt, 602
Constable (Samuel), Geometrical Exercises for Beginners, 457
Constance, the Lake of, 348
Consumption, Physiognomy of, Francis Galton, F.R.S., and Dr. F. A. Mahomed, 389
Copper, on the Electrolysis of Sulphate of, G. Gore, LL.D., F.R.S., 473
Coral, Precious, Prof. H. N. Moseley, F.R.S., 510; Prof. Henry Hillyer Giglioli, 552
Cordoba, Observatory of, 349
Corfield (W. H.), Fumifugium, 151
Corridors of Time, a Glimpse through, Prof. Robert S. Ball, LL.D., F.R.S., 79, 103; Dr. A. Dupré, 217; Prof. T. H. Huxley, F.R.S., 241
Costa Rica, Earthquake in, 471
Costerus (Dr. J. C.), Seasonal Order in Colours of Flowers, 481
Cricket's Chirp varying with the Temperature, 229
Cross (C. F.) and E. J. Bevan, Chemistry of Bast Fibre, 351

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

THURSDAY, NOVEMBER 3, 1881

A RECENT "FIND" IN BRITISH PALÆONTOLOGY

THE world is but rarely startled nowadays by the discovery of whole groups of new organisms from the rocks of Britain; it is only from the Far West that such surprises come. Two or three generations of active collectors have ransacked our strata so thoroughly that only now and then by some happy chance is a new vein of research opened, the finder of which may be congratulated rather on his good luck than on his special acuteness in observation. Such a vein has recently been struck by the Geological Survey among the Lower Carboniferous rocks of the south of Scotland. Some account of the more important features of this "find" may be of interest to the general reader.

Travellers who enter Scotland from the south, remark that after leaving the plains of the Tweed on the east side, or those of the Solway on the west, they find themselves in a range of hills or uplands, not lofty and picturesque indeed, but with sufficient height and individuality of feature to form a notable barrier between the valleys of the border on the one hand and the Scottish Lowlands on the other. This belt of pastoral high grounds, so bright with the glamour of poetry and romance, has a special interest to the geologist. He can trace it back to its origin about the close of the Silurian period, when it first began to rise out of the sea, and served, by its upheaval, to define one or more of the great inland basins in which the Old Red Sandstone was deposited. From that ancient time down to the present the ridge seems to have formed a barrier between the basins on its northern and southern margin. No doubt it has been enormously worn down in the general denudation of the country, deep valleys have been trenched through it; much of it has now and again been submerged and covered by masses of sedimentary material. Nevertheless it has preserved its existence. Lying along a line of terrestrial weakness, its strata, originally horizontal sheets of mud and sand, piled over each other to a depth of many thousand feet, have been crumpled and corrugated to a vast extent. The movements by which these contortions were produced have doubtless recurred at many intervals, so that we may conceive them to have in some measure, if not entirely, compensated by occasional elevation for the lowering of the level of the ridge by continuous denudation.

During the early part of the Carboniferous period these southern Silurian uplands of Scotland formed a barrier between the lagoons of the Lowlands and the more open waters to the south which spread over the north and centre of England. That the ridge was not continuous, or at least that there was now some water-way across it or round its end, between the basins on either side, is indicated by the similarity of their fossils. Yet that it formed on the whole a tolerably effective barrier is indicated partly by the marked difference between the corresponding strata on its northern and southern flanks, and partly by the singular series of organic remains to which attention is here called.

For some years past the Geological Survey of Scotland has been engaged in the detailed investigation of the Carboniferous rocks between the Silurian uplands and the English border. The whole region has now been mapped; the maps are partly published, and partly in the hands of the engraver for speedy publication. The rocks have been collected, and their chemical and microscopic analysis is in progress. Their fossils have been gathered from every available stratum, and have already been in large measure named and described. So that materials now exist for a tolerably complete review and comparison of the stratigraphy, petrography, and palæontology of the Carboniferous rocks of the Scottish Border. In the course of the work one particular zone of shale on the banks of the River Esk has been found to possess extraordinary palæontological value. From this stratum where exposed for a few square yards by the edge of the river a larger number of new organisms has been exhumed by the Survey than has been obtained from the entire Carboniferous system of Scotland for years past. As a whole the remains are in an excellent state of preservation. Indeed in some instances they have been so admirably wrapped up in their matrix of fine clay as to retain structures which have never before been recognised in a fossil state.

The more important treasures from the shales of Eskdale and Liddesdale are fishes, crustaceans, and arachnids. The fishes were at once placed in the hands of Dr. R. H. Traquair, whose devotion to fossil ichthyology has made him our *facile princeps* in this department of palæontology. The first part of his report on them, devoted to the Ganoidei, has been completed and is published by the Royal Society of Edinburgh (*Trans. Roy. Soc. Edin.* xxx. (1881), p. 15). He points out the extraordinary interest of the collection, both as opening up an almost entirely new fish-fauna, and as revealing remarkable structural peculiarities in many of the new forms. Out of twenty-eight species of ganoids no fewer than twenty at least are new. Of the sixteen genera in which these species are comprised five are now for the first time added to science (*Phanerosteon*, *Holurus*, *Canobius*, *Cheirodopsis*, and *Tarrasius*), of which one (*Tarrasius*) is altogether so peculiar that no place can be found for it in any known family. To the family of Palæoniscidæ fifteen new species and three new genera are added. The most abundant species is a form of *Rhadinichthys*, which occurs also on the north side of the Silurian barrier. Another fish of common occurrence in the latter region is *Eurynotus crenatus*, of which only a single scale has been found in the Eskdale and Liddesdale region. A third species common to the two sides of the barrier is probably *Wardichthys cyclosoma*. But with these and possibly one or two other exceptions, all the fishes in the southern area are as yet peculiar to it, while at the same time the common forms of the Lothians are conspicuous by their absence in Eskdale and Liddesdale. These facts suggest interesting problems in Carboniferous geography and in ancient zoological distribution.

Without entering here into structural details, we may refer to the peculiarities of one or two of the new forms described by Dr. Traquair. He proposes the term *Phanerosteon* for a genus of Palæoniscid fishes, possessing a fusiform body, apparently for the most part devoid of scales, with a peculiarly rounded off dorsal fin, and destitute of fin-fulcra. If the nakedness of the body be due not to the non-preservation of scales, but, as seems almost certain, to the original absence of them, we are here presented with a Palæoniscoid fish showing a condition of squamation almost identical with that of *Polyodon*. Only one species, but a number of specimens of it have been obtained. The new genus *Holurus*, though placed by its author among the Palæoniscidæ, offers in its non-bifurcated caudal and rounded long-based pectoral fin a contradiction to his definition of this family; but the cranial osteology is in the main so decidedly Palæoniscid that he prefers to regard the genus as standing most fittingly where he has put it. Two species are described. Still more aberrant from the typical Palæoniscidæ is the genus *Canobius*, which to the general configuration of the family unites a disposition of the suspensorial and opercular apparatus almost identical with that of the same parts in the Platysomid *Eurynotus*. Four species are described. But the most remarkable of all this singular group of fishes is included by Dr. Traquair in a new family, to which, from the more characteristic of two specimens having been found at the foot of the Tarras Water, he has given the name of Tarrasiidæ. *Tarrasius*, the typical and only known genus possesses rhombic, minute, shagreen-like scales, persistent notochord, well ossified neural and hæmal arches and spines, with the slender interspinous bones penetrating between the extremities of the vertebral spines as in teleostean fishes, and a long dorsal fin composed of closely-set jointed rays. Only two specimens, conjectured to belong to the same species, have as yet been obtained. Their state of preservation is such as to leave in doubt some important parts of the structure of this curious fish. It is to be hoped that future exploration in the same prolific locality may furnish Dr. Traquair with additional evidence on the subject, and enable him to complete his work.

Associated with the skeletons of the fishes are the remains of some new phyllopod and decapod crustaceans, which have been worked out by Mr. B. N. Peach, the Acting Palæontologist of the Scottish Geological Survey, who has described them in a memoir also communicated to the Royal Society of Edinburgh (*Trans. Roy. Soc. Edin.* vol. xxx. (1881) Part 1). The Phyllopods consist of two new species of *Ceratiocaris*, which differ from the Silurian species of this genus in having the body relatively much larger than the carapace. The numerous specimens are in a good state of preservation, one individual having been found with its intestinal canal distended with food. Of Macrurous Decapods several new species occur that differ in no essential respect from their living representatives. They belong to the genera *Anthrapalæmon*, *Palæocrangon*, and *Palæocaris*, upwards of forty specimens of one species of *Anthrapalæmon* having been obtained. Mr. Peach has worked out their structure with great skill. Among his observations is the occurrence of abundant minute calcareous calculi on the tests of these crustacea, precisely like those of the common shrimp.

One of the most singular features in our recent additions to the palæontology of the Lower Carboniferous rocks of the Scottish Border is the abundance in which the remains of scorpions have been discovered. The existence of these arachnids (*Eoscorpius*) in strata of this age in Scotland was made known some years ago by Dr. H. Woodward. But we are now in possession not of mere single and imperfect fragments, but of numerous and often admirably-preserved specimens which have enabled Mr. Peach to work out the structure of the insects in great detail. In anticipation of the early publication of his descriptions the following notes may be given here. He finds that these Palæozoic forms differ in no essential respect from the living scorpion so far as regards external organs. He has recognised in them every structure of the recent form, down even to hairs and hooks on the feet. The sting alone has not been certainly observed, but that it existed may be inferred from the presence of the poison gland which Mr. Peach has detected in the fossil state. The chief difference between the living scorpion and its ancient progenitors lies in the fact that in the fossil forms the mesial eyes are much larger in proportion to the lateral ones, and also to the size of the whole animal. The two mesial eyes are placed on an eminence near the anterior margin of the carapace formed by two converging tubes, and so arranged that the creature could look with them upwards, outwards, and forwards. There are at least four lateral eyes on each side. The mandibles, palpi, and four pairs of walking legs are beauti-

fully distinct on many specimens. The combs are much like those of the modern scorpion, but with a very remarkable sculpturing which at once recalls that so characteristic of the Eurypterids. The genital orifice, combs, and eight breathing stigmata occupy positions similar to those of the same organs in the modern scorpion. As regards theories of descent these fossils afford no more help in tracing the pedigree of the scorpion than is furnished by the living form, for it is obvious that the scorpion has remained with hardly any change since Carboniferous times. There can be little doubt that it is the most ancient type of Arachnid, whence the others have been derived.

Since the first specimens of scorpion were found by the Geological Survey among the Lower Carboniferous beds of the Border further research has brought many more to light from other and distant parts of the country. No fewer than five species belonging to a single genus (*Eoscorpius*) have been recognised by Mr. Peach, some of which must have contained individuals eight or ten inches in length. Most of these specimens, and also the crustacea and fishes above referred to, have been obtained by the Survey fossil-collector, A. Macconochie.

One further interesting fact deserves mention here. When the Geological Survey first began its work in Scotland, and was engaged in mapping the east of Berwickshire and Haddingtonshire, a remarkable and hitherto unique specimen was found there which was described by Salter under the name of *Cycadites Caledonicus*, as the most ancient cycad yet known. Among the specimens recently collected by A. Macconochie from the Border ground are several apparently of this same form which are so well preserved as to show that they are not plants at all. They occur together with species of *Eurypterus*, and are almost certainly a yet undescribed comb-like organ belonging to that creature. This fact, coupled with the singular eurypterid-like sculpture on the combs of the fossil scorpions, lends support to the suggestion which has been made that the eurypterids are ancestral aquatic arachnids.

ARCH. GEIKIE

THE HEAD-HUNTERS OF BORNEO

The Head-hunters of Borneo: a Narrative of Travel up the Mahakkam and down the Barito; also Journeyings in Sumatra. By Carl Bock (late Commissioner of the Dutch Government). With thirty Coloured Plates, Map, and other Illustrations. (London: Sampson Low, Marston, Searle, and Rivington, 1881.)

THIS large and lavishly-illustrated volume derives its chief value from the fact that the author is a clever [ar]tist, and that all the handsome coloured plates which [fo]rm the main feature of the book are evidently careful [dr]awings made on the spot, not imaginary designs con[stru]cted from more or less imperfect sketches or descrip[tio]ns. The houses, villages, and forest scenes are all true [to] nature, and the same may be said of the numerous [po]rtraits of the Dyaks and illustrations of their domestic [lif]e and customs. The figures are indeed wonderfully [lif]e-like and the drawing accurate, the only fault being [a] very slight tendency to Europeanise the features—a [ki]nd of personal equation due to Mr. Bock's artistic [stu]dies having been made from European models. This is visible in the small and well-formed mouths of the two women in Plate 16, and in the perfectly straight and well-developed nose of the "Chief of the Forest People" in Plate 24. When, however, he has taken special pains and has had ample time to finish his drawing, as in "Hetdung, my favourite Dyak Boy" (Plate 23), he avoids this fault, and gives us a portrait as perfect and as characteristic as a good photograph.

Mr. Bock went out to the East to collect birds in Sumatra for the late Marquis of Tweeddale, and spent about nine months in that island. He was then employed by the Dutch Government to make an excursion through the interior of Borneo, to report on some of the Dyak tribes and collect specimens of natural history for the museums of Holland. This journey, which occupied in its preparation and execution about six months, was partly over ground new to European travellers; first to the country of the Poonau Dyaks in about 1° 40′ N. lat., 116° 30′ E. long., and then up a western tributary of the Mahakkam or Koti River, and overland for a short distance to the head waters of the Teweh, a branch of the Barito or Banjermassin River. This watershed is in about 0° 5′ S. lat. and 115° 35′ E. long., and appears to consist of an undulating country with a few detached hills. It is however marked by a curious geological phenomenon very rarely met with in the tropics, a large area covered with huge angular rocks, of every shape and size and tossed about in the greatest confusion. It is called by the natives *Jalan batu*, or the Stony way, and our author's description of it will bear quotation:—

"Covering an area of several square miles, and cropping up as it were in the centre of a vast forest, this Field of Stones is well calculated to arouse the superstitious dread of a savage people. Here scattered in wonderful confusion like the remains of a ruined castle: there standing erect and orderly as if carved by chisel and levelled by plumb-line and square: some in ponderous masses as large as a house, fifty or sixty feet in height and of still greater width and thickness: others heaped like so many petrified cocoa-nuts, or like a pile of forty-pounder cannon-balls: here bare and gaunt like the pillars of Stonehenge: there moss-covered and decked with ferns or gorgeous flowers: in all directions for miles and miles the stones lie scattered. Some of them have assumed fantastic shapes, in which the imagination can easily picture a travesty of the human form, or of other familiar objects: others again are marked with quaint devices, where wind and rain have put finishing touches to natural cracks and crevices, and made them assume the appearance of deliberately carved inscriptions, like those seen on ancient weather-beaten tombstones—or rather, like the curious 'picture-writings' found on scattered stones and rocks in British Guiana and other parts of South America. . . . For miles our route lay through this wilderness of sterility and fertility combined—sometimes creeping between two parallel walls of stone, thrown so closely together that there was scarcely room to walk sideways; sometimes making a considerable *détour* to avoid a more than usually rough spot. In some places the earth was covered with small loose stones, most difficult and painful to walk over; in others, the ground seemed to be of solid rock, and great care was necessary in walking to prevent one's feet being fixed in one of the innumerable crevices, which were the more dangerous from being partially covered by vegetation. Many of the large stones were so lightly balanced on a small foundation that it seemed as if the exercise of a moderate force would be sufficient to overturn them."

Mr. Bock was at first inclined to attribute this phenomenal region to volcanic agency; but, considering that no earthquakes or volcanic phenomena occur throughout Borneo, and that these rocks are all "a rubbly limestone," he concludes that they owe their origin to "the denuding force of the torrential tropical rains, which have gradually bared the limestone deposit." This however is a very lame conclusion, and in no way accounts for the extraordinary way in which the rocks have been fractured and heaped over each other. The only sufficient explanation is to be found in the action of subterranean waters dissolving away the limestone rock and thus forming extensive caverns, the roofs of which have at length fallen in over a large area, and thus produced the unmistakable appearances of violent upheaval and fracture. This phenomenon is however very rare on so extensive a scale, and, so far as we can recollect, this Bornean "field of stones" is almost unique. The nature of the surrounding country is not described, but the locality appears to be a low and nearly level watershed between the lateral tributaries of two great river systems, so that there might be a subterranean drainage in two directions. In many other parts of Borneo there are indications of long-continued denudation, and it may be that the very absence of volcanic phenomena, and the consequent stability of the surface for long periods, has rendered possible the amount of uninterrupted subterranean denudation required to produce this mimic representation of great volcanic convulsions.

Mr. Bock gives us a pretty full account of the Dyak tribes of Southern Borneo and all that he could learn about them, and the general impression of his descriptions, aided by his life-like portraits and domestic scenes, is, that there is a wonderful similarity between all the chief tribes of this great island both in physical and mental characteristics, though there are many specialities in habits. In the south we find a decided indication of Pacific influence in the general practice of tattooing, in the custom of *pomali* or "taboo," and perhaps even in the practice of cannibalism by one tribe—the Tring Dyaks. In the south, too, the use of the blow-tube seems to be almost universal, whereas it is comparatively rare in the north; but in their general character and habits, customs, ideas, and superstitions, there is a practical identity which renders much of Mr. Bock's volume a repetition of what has been more fully and accurately described by St. John, Grant, and other writers.

We may however note a few of the more novel or interesting facts recorded Mr. Bock never saw an orang-utan, so that this animal is evidently far less abundant in the southern than in the north-western parts of the island. He describes the effects of a great drought in 1878—a year before his visit—which destroyed the forest-trees over large areas and caused the destruction of birds and game, and the failure of crops, to such an extent as to cause a famine, and this on the equator in an area of dense forest where rains are usually of almost constant occurrence. Almost the only amusing episode in the book is the account of an earnest attempt to discover the much-talked-of "tailed men" of Borneo. Tjiropon, an old and faithful servant of the Sultan of Koti, declared, in the Sultan's presence, that he himself had seen some of these people in the Passir country. He called them "Orang-bontoet," or tailed men, and added the usual statement, that the tail was from two to four inches long, and that the people cut holes in the floor to receive it, so that they could sit down comfortably! Mr. Bock thought this so absurd that he disbelieved the whole story, but the Sultan of Koti was greatly impressed by it, and it was decided to despatch Tjiropon on an embassy to the Sultan of Passir with a letter requesting him to send by the bearer two of the "Orang-bontoet." After a long absence he returned, and met the party at Banjermassin as agreed; but he was very crestfallen, and would say nothing except that he had delivered the letter, and had not been able to procure any tailed men. Thereupon the Resident of Banjermassin, at Mr. Bock's request, himself sent a party to Passir with a letter to the Sultan, requesting him to say if there really were any tailed men in his country, and what had happened to the former messenger. After twenty-five days' absence the party returned, with a message from the Sultan of Passir explaining the whole matter. It appears that the Sultan's personal attendants are known by the term "Orang-boentoet di Sultan di Passir"—literally "the tail-people of the Sultan of Passir." The Sultan declared he had never heard of any other "orang-bontoet." He was very angry at two of his suite being so unceremoniously asked for, and ordered the messenger to depart instantly on pain of being flogged—a threatened indignity which sufficiently accounted for poor Tjiropon's silence. When again spoken to, however, he exclaimed,—"Before Allah! I *have* seen the *Orang-bontoet* long ago, and have spoken to them, but I could not see them this time."

Among the few natural-history facts noted, are, the conspicuousness of the wild bees' nests "at variance with the almost universal habit among all animals to conceal their nests as much as possible." But these nests evidently come under the category of objects which exhibit warning colours, being sufficiently protected by the stings of their inhabitants. The remarkable tenacity of life of the *Loris tardigradus* is well illustrated in the following passage:—

"One day I wounded one, and knowing its tenacity of life I strangled the little animal, then cut it open and pierced its heart. An hour elapsed before I waited to skin it, and when I took down the body I found it still alive, its lovely eyes wide open. When, hoping to finally despatch it, I pierced its brain with a needle, it began to shriek, and still some minutes elapsed before it was actually gone."

An equal tenacity of life is found in the allied Galeopithecus, which could be killed neither by breaking the spine nor piercing the brain, and it is not improbable that the continued survival of these very ancient types in the midst of higher forms may be in part due to this extreme power of endurance.

The journal of the Sumatra expedition contains little of importance, and all that is new or valuable in the volume might have been well compressed into a couple of magazine articles or papers for the Geographical Society. The illustrations however furnish the real *raison d'être* of the book; and besides the portraits of natives already referred to, attention may be called to the plate "Crossing the River Benangan," which gives the very best and most accurate idea of an equatorial forest that the present writer has ever met with.

ALFRED R. WALLACE

BUTTERFLIES

Butterflies: their Structure, Changes, and Life-Histories, with Special Reference to American Forms. Being an Application of the "Doctrine of Descent" to the Study of Butterflies. With an Appendix of Practical Instructions. By Samuel H. Scudder. (New York: Henry Holt and Company, 1881.)

MR. SCUDDER'S great reputation as an entomologist will cause many readers to turn to this beautifully got up volume with eager curiosity. They will expect to find a tolerably full account of all those interesting and complex phenomena of metamorphosis, variation, dimorphism and polymorphism, protective colouration, mimicry, and distribution, for the elucidation of which no class of organisms offers such abundant and striking materials; while they might not unreasonably anticipate that the bearing of the whole series of these phenomena on the "Doctrine of Descent" would be clearly indicated and the necessary conclusions to be drawn from them strongly insisted upon. The first separate work ever published on the general history of butterflies, as distinguished from their classification or specific description, would naturally excite some such expectations as these; but those who have entertained such ideas will be disappointed, and may perhaps be inclined to give the book less credit than it really deserves. We will therefore briefly indicate its contents and point out a few of its merits and deficiencies.

The first four chapters—"The Egg," "The Catterpillar," "The Chrysalis," and "The Butterfly"—respectively, give a very good general account of the form and structure of the insect during the stages of its existence, and they are illustrated by a large number of very excellent woodcuts, many of which seem to be original. Then follow descriptions of the internal organs, and their transformations during development, and a good chapter on habits, illustrated almost exclusively from North American species. We now come to the more important and interesting part of the volume, and find chapters on "Seasonal Changes and Histories," "The Colouring of Butterflies," "Diversity of the Sexes in Colouring and Structure," "The Origin and Development of Ornamentation," "Ancestry and Classification," and "Geographical Distribution," the titles of which cover a wide range, and seem to include all the chief points required for a full exposition of the subject. The treatment however is by no means satisfactory, since it is a rare thing to find any fact even alluded to beyond the range of North American species; and though the valuable observations of Edwards and Riley are frequently referred to, the important researches of Weismann and Fritz Müller are hardly mentioned. Far more important however is the almost total silence on the whole question of protective and warning colouration in larva and perfect insects and the wonderful phenomena of mimicry, which play so large a part in determining both the forms and colours of insects all over the world, and which are so marvellously developed in butterflies. The absence of all these considerations renders the chapter on "The Origin and Development of Ornamentation" most unsatisfactory, since it is almost wholly devoted to suggestions as to the probable lines which have been followed in the development of the ornamentation, while we are left without any clue to the reasons for such special and wonderfully diversified results, or the laws by which they have been produced. Equally meagre is the chapter on "Geographical Distribution," which is treated solely from the point of view of the North American collector.

A more important fault than these deficiencies, in a work presumably intended for popular reading and to excite young American entomologists to a more complete study of their subject, is the very peculiar system of nomenclature adopted by the author, which, by the needless difficulties it will cause, must tend to disgust beginners with the whole study of natural history. The writer who has done more than any other person to facilitate the study of North American butterflies is Mr. William H. Edwards, who, besides a great work on "The Butterflies of North America," illustrated by fine coloured plates, has published, so recently as 1877, a complete "Catalogue" of the species. He is in fact *the* authority on North American butterflies, to the conscientious study of which he has devoted his life. When any such standard systematic work exists in a country, it seems to us the obvious duty of all who write popular books to follow its classification and nomenclature, not as endorsing their correctness, but simply to facilitate reference to works which every student *must* constantly refer to. Instead of doing so Mr. Scudder follows a quite different order in his systematic list of species, adopts a complex system of families, sub-families, tribes, and genera, mostly with unfamiliar names; and uses a generic nomenclature so totally unlike that of the above-named standard work, that out of a list of fifty-eight genera referred to in his volume only ten have the same names as those adopted by Mr. Edwards. As an example of the difficulty and confusion this must cause to a beginner we may mention that the North American species of the old genus Papilio are here given under five distinct generic names; Lycæna under the same number, and Argynnis under four. The family Papilionides, which Mr. Scudder retains, no longer contains the genus Papilio, after which it is named, because he transfers this name to our old friend the Camberwell Beauty, which he styles *Papilio Antiopa*. The old Satyridæ, or Meadow Browns, are now named Oreades, and they are placed at the head of all the butterflies instead of near the end, as in the works of Edwards and of all the old writers. This must be all the more puzzling, because throughout the body of the work these names are everywhere given without the least indication that they are not in universal use. Thus at pages 100–102 we have *Basilarchia Archippus* many times mentioned, with a reference to Riley. But that author always uses the old name *Limenitis disippus*, and in the copious index to his Missouri Entomological Report, just issued, the name Basilarchia is not to be found, neither does it appear, even as a synonym, in Mr. Edwards' "Catalogue"! No one will object to differences of opinion on questions of nomenclature, when kept to their proper place in strictly scientific treatises; but every one who has at heart the extension of a taste for natural history has a right to protest against such totally unnecessary difficulties being thrown in the path of beginners.

We regret having to speak so strongly in animadversion of a book which contains much interesting matter and much valuable information, which is written in a pleasant

style and is illustrated in a very attractive manner. But we feel that an opportunity has been missed of producing a volume which should open up one of the most marvellous pages in the book of nature, in a manner to interest a wide class of readers and attract many new votaries to the study of these most beautiful and in many respects most instructive members of the great class of insects.

OUR BOOK SHELF

The Quarterly Journal of Microscopical Science. (London: Churchill.)

THE twenty-first volume of the second series of the above journal—published during the four quarters of this year—lies in its complete form before us, and it seems to merit more than a passing record at our hands. The volume contains over 650 pages of text, and, besides woodcuts, thirty-four plates, many coloured, and the majority of double size; but it is not the quantity of the material, gratifying though it be to see that the British school is not wanting in this respect, so much as the quality of the contributions that we would call attention to. In the importance of its Memoirs this journal, now in its majority, may fully claim to rank on the level of the highest of those comparable to it published in Germany, and its editor and his assistants are to be congratulated on seeing that all the subjects coming under their province are so fairly dealt with. It is not proposed to treat here of the individual memoirs from a critical point of view—no one individual could write such a criticism—but as a general *résumé* of the work done. Slightly classified, vegetable histology and physiology is enriched by the papers on *Welwitschia mirabilis* by F. Orpen Bower; on the development of starch grains, by F. W. Schimper; on the water glands in the leaf of *Saxifraga crustata*, by W. Gardiner. As contributions to zoology may be mentioned the memoir by G. Busk on Polyzoa; by H. B. Brady on Reticularian Rhizopods; a most important paper on Limulus an Arachnid, by the editor; to embryology the researches of Lankester on Limnocodium, Scott on Lampreys, Wilson on Actinotrocha; to anatomy the memoirs, on the head cavities and nerves of Elasmobranchs, by Dr. Marshall; on the nasal mucous membrane, by Dr. Klein; on the Branchiate Echinoderms, by Herbert Carpenter; on the organ of Jacobson, by Dr. Klein; on the lymphatic system of the skin and mucous membrane, by Dr. Klein; on the Wolffian duct and body in the chick, by Adam Sedgwick; on the cranial nerves of Scyllium, by A. Milnes Marshall; and on the structure and significance of some aberrant forms of Lamellibranchiate gills, by Dr. K. Mitsuri. Nor must the papers by Mrs. Ernest Hart on the micrometric numeration of the blood corpuscles; by J. F. Dowdeswell on some appearances of the blood corpuscles; nor those by Dr. Cunningham on microscopic organisms in the intestinal canal, and Prof. Lister on the relations of micro-organisms to disease, be overlooked. The value of this volume will thus be apparent to the reader who knows of the subjects of which the above is a condensed list. One thing alone, to our mind, the volume needs, viz. a really efficient index to its valuable contents. The two pages and a half of index to these 650 pages of matter form an index only in name. Would it not be well to have an index volume published to the twenty-one volumes of this series, and then with volume xxii. commence a yearly index which would be both a help and a service to the student?

Essays on the Floating-Matter of the Air in Relation to Putrefaction and Infection. By John Tyndall, F.R.S., LL.D (London: Longmans and Co., 1881.)

TO reprint these essays in an easily-accessible form was a happy thought of the author's. It is of vast importance to the public at large that they should at least know what views are being held by a large majority of working and thinking men on the subjects of putrefaction and infection. Quite apart from the question of how germs originate is the question of what evils arise from their presence; and although, with most of those who have investigated the matter, we regard it as well proven that, except from a pre-existing germ, no new germ arises, yet we would be prepared almost to overlook this part of the matter in our anxiety to see proper notions diffused as to the effects produced by these "floating matters of the air." The benefits that mankind has gained by the researches of the biologist, chemist, and physicist into this subject are already beyond calculation; nor is there yet any apparent limit to them. From the pages of this small volume some ideas may be gleaned of what the modern treatment of surgical cases has gained by a knowledge of this subject; nor do we think the day far distant when medicine may reach to the rank of surgery through an insight into the germ causation of febrile disease. The history of the silkworm disease in Italy and France bears witness to the enormous value, even if measured in a commercial sense, of the labours of Pasteur, Quatrefages, and others in working out from this point of view the parasitic diseases that caused at one time the almost total destruction of the silk industry in Europe; and the history of Pasteur's researches on fermentation, even when told in a few words, as in the fourth chapter of this volume, does it not tell of discoveries full of benefit to one portion at least of mankind? Prof. Tyndall well writes: "The antiseptic system of surgery is based on the recognition of living contagia as the agents of putrefaction." Keep these away, destroy them either by an excess of cold or heat, and the putrefaction is prevented. But this is true not of surgery only; it makes itself felt in the routine of every-day life. An account was laid before the Academy of Sciences of Paris, in May of this year, of an examination of the feeding-bottles in use at a *crèche* in Paris. The milk for the children put into these contracted a nauseous odour. Of thirty-one examined, twenty-eight contained in the caoutchouc tubes or nipples germs (microscopical microbes), and even in some cases there were masses, more or less abundant, of fungoid vegetations. The milk found remaining in some was acid, with numerous bacteria; and this in spite of what was thought to be cleanliness. No wonder Prof. Tyndall writes of such material—such matter out of place—as dirt. We cannot all contrive to live in the grand, pure air to be found in such places as the Bel Alp; but all could help towards making the air of their dwellings freer from the contagion of dirt; and if right and accurate notions were held on such matters by all interested in them, prevention would soon be seen to be much better than cure. This little volume will be found exceedingly interesting reading, and its contents will furnish the reader with abundant material for thought, which perhaps may, in floating through his brain, take root there and bring forth a crop of good fruit.

E. P. W.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Struggle of Parts in the Organism

MR. ROMANES, in his letter published in your number of Oct. 27 (vol. xxiv. p. 604) draws a distinction between the "Argument from Design as elaborated by the Natural Theologians of the past generation," and another argument from design which he

attributes to me, and which he describes as a "metaphysical" teleology—the idea of "an ultimate design pervading all nature, and blending into one harmonious Cosmos the combination and co-ordination of physical causes."

The first of these arguments from design he says he has a right to contest in your columns and to represent as "subverted" by Mr. Darwin: whilst as regards the second of these arguments from design, he admits the truth of my position that "no possible amount of discovery concerning the physical causes of phenomena can affect it."

I am not able to accept this distinction, or to withdraw on the strength of it my protest against the original communication of Mr. Romanes. The distinction is, in my opinion, purely imaginary and fallacious. The fundamental proposition of all arguments from design is simply this: that the exquisite adaptations to special ends which are conspicuous in organic nature are, and can only be, the work of physical forces when these are under the combination and direction and control of Mind.

But the whole force of this general proposition, and the whole power of it to produce conviction, depends on its applicability to particular cases of adaptation. There may be, and there are in nature, a few cases of apparent adaptations and of orderly arrangements of a very simple kind which do not necessarily suggest Mental Purpose. They may be the effect of what we call accident, or of the action of elementary laws under no guidance or direction. Inorganic phenomena furnish many examples of such arrangements. Even among organic things there may be a few examples of them. But in the special and elaborate adaptations of organic structures to their particular work and function, the human mind recognises the operation of mental faculties having a fundamental analogy with its own. Mind is a known agency, producing well-known effects. These effects can be recognised with as much certainty as the effects of any material force acting by itself. The Argument from Design is founded on this recognition. The writers of the last generation were perfectly right in resting the general Argument from Design on the separate instances of adaptation in which the mark of Mind is most signal and conspicuous. I hold, as they held, that each particular instance of adaptation which cannot be due to chance, and which cannot be due to the uncombined action of elementary forces, is "a separate piece of evidence pointing to operations of special design."

Mr. Darwin's theory of Natural Selection no more touches this argument than his hand could touch the fixed stars.

When Sir Charles Bell wrote his beautiful and classical Treatise on the Hand, he knew that the hand of every individual man has been "developed" in the womb. He knew that in the course of that development it passed through many successive stages. He knew that the vital processes concerned in this development were organic processes forming part of "natural law." But it never occurred to him to imagine that the "law" under which such intricate and wonderful adaptations were reached was a "law" in which Design had no part, or over which Mental Purpose had no control. He saw in physical causation the instrument of Mental Purpose, and not its rival or its enemy. He knew, moreover, the close relations between the hand of man and the less perfect, but the equally adapted structures of the same limb in the lower animals. He knew, farther, that the theory of Evolution had been started, and that just as individuals were born and grew, so it was suggested that all Animal forms had been born of each other, and that the Human Hand was the result of a long gestation in the womb of Time. He alludes to these theories and sets them aside—not as being untrue, but as being immaterial to his argument. And he was right.

Mr. Romanes is much mistaken if he supposes that the present generation is satisfied with the purely materialistic explanations of adapted structures which are erroneously supposed to be the final result of Mr. Darwin's theory. So thoroughly dissatisfied, on the contrary, with these explanations is the mind of the present generation, that it is breaking out in revolt against them along all the line. The old school of Theism is as alive as ever, and is as ready as ever to appropriate every new fact into the structure of its well-worn defences. And outside this school—among men who reject Christianity altogether, and who sit loose from every known theology—a conviction has arisen that somehow—by whatever name it may be called—Mind is indeed "immanent" in nature, working everywhere with an awful and an abiding Presence.

This view has been supported of late in Germany in a powerful argument by an author whose philosophy may seem grotesque, but who certainly has at his command all the resources of scientific knowledge, and who accepts and incorporates every fact which has been established in the whole field of biological investigation.

I wish Mr. Darwin's disciples would imitate a little of the dignified reticence of their master. He walks with a patient and a stately step along the paths of conscientious observation. No fact is too minute—no generalisation is too bold. But for the most part the whole is kept well within the limits, actual or supposed, of physical causation, and the rash dogmatism on higher questions of Philosophy and Theology which are common among his more fanatical disciples, are "conspicuous by their absence" in his writings. ARGYLL

It will be instructive to many, I doubt not, as to myself, to receive from Mr. Romanes an explanation of the precise sense which he attaches to the phrase "a general law whose operation is presumably competent to produce" any set of phenomena.

No one is more desirous than I am to see science freed from all theological complications; and it seems to me that every one who speaks of laws as "governing," "controlling," "regulating," or "producing" phenomena, is really mixing up ideas belonging to two entirely distinct categories.

That in the *purely scientific* sense, a "law of Nature" is nothing more than a general expression of a certain set of uniformities which the intellect of man discerns in the surrounding universe—that such a law holds good just so far as it has been verified, and not necessarily any further—that it accounts for nothing, and explains nothing—and that the power of prediction which it is supposed to give, depends entirely on an *assumption* of its universality, which may or may not be justified by facts—was the teaching of the great masters (Herschel, Whewell, and Baden-Powell), who aimed to form correct habits of thought among what half a century ago was the "rising generation" of scientific men. And as all subsequent writers on the logic of science, from J. S. Mill to W. Stanley Jevons, have taken the same view, I venture to think that it rests with Mr. Romanes to show that there is anything in the *law* of Natural Selection (which is simply the generalised expression of the *fact* of "the survival of the fittest"), that places it in a different category from every other.

The whole series of expressions to which I have taken exception may be regarded either as a "survival" of the theological conceptions by which science was formerly dominated, or as the result of a very common confusion between a "law" of science and a "law" of a state. For a "law" can only "govern," "control," "regulate," "produce," or exert any kind of *coercive* agency, when there is a power to give it effect; the "law," in that sense, being simply the expression of the will of such governing power, divine or human, as the case may be.

But as science (and in this I am quite at one with Mr. Romanes) knows nothing of such "metaphysical" conceptions, I cannot but think that it would be much better that scientific language should be cleared from expressions that have no meaning at all, if it be not one based upon them.

If I have not made my meaning sufficiently clear, I may refer any one who wishes to see this matter more fully discussed to my paper on "Nature and Law," in the *Modern Review* for October, 1880. WILLIAM B. CARPENTER

56, Regent's Park Road, N.W., October 29

P.S.—I regret that my reference to what Mr. Simon (in his address on Public Medicine at the International Medical Congress) designated as "the very remarkable series of facts" adduced by Dr. Creighton in support of his view of the communicability of bovine tuberculosis to man through the medium of milk, should have been so worded as to make it appear that Dr. Creighton accepts the doctrine of Klebs as to the "micrococcus" origin of tubercle, his dissent from which he had explicitly recorded. As Mr. Simon spoke of Klebs' doctrine as having been "solidly settled and widely extended" by the recent researches of Schüller, and as Dr. Creighton's difficulty of conceiving "a neutral (?) living organism" to be "charged with the power of conveying complex details of form and structure from one body to another," affords no *dis*proof of it, there seemed to me no occasion, in writing for the general public, to take any special notice of a point which Mr. Simon, in addressing a professional audience, had thought it better to pass without mention.—W. B. C.

An Alleged Diminution in the Size of Men's Heads

ALLOW me to draw the attention of your readers to a statement which is certainly strange, if true. An opinion is prevalent in the hat trade that the size of men's heads has undergone a decrease within the last thirty or forty years. The following statement has been given to me by a hatter whose name has attained a pre-eminence of a duration of more than one generation. "Five-and-thirty years ago," he says, "when I was a young man, we used to purchase hats for retail trade in the following ratio:—

Sizes	$21—21\frac{1}{2}—22—22\frac{1}{2}—23—23\frac{1}{2}$ inches.
Relative number ...	0— 1 — 2— 4 — 3— 1

At the present time," he adds, "I am selling hats in this ratio:—

Sizes	$21—21\frac{1}{2}—22—22\frac{1}{2}—23—23\frac{1}{2}$ inches.
Relative number ...	3— 4 — 3— 1 — 1— 0"

A manufacturer writes: "I should say that heads generally are two sizes less than at the time you refer to. A head of more than twenty-four inches' circumference is now quite a rarity, whilst we make thousands of hats for heads with a circumference of about twenty-one inches." I have received similar statements from other members of the trade, both wholesale and retail, and therefore feel that no further apology is required for bringing them under your notice. Accepting the statement *quantum valeat*, I have endeavoured to ascertain whether I could find any explanation or confirmation thereof. I have not succeeded, and therefore venture to ask information or opinions through your columns. The statement comes to me not only from men of experience in the trade, but from men of intelligence and observation exercised beyond the limits of the shop or the factory. It is, I am informed, extensively believed among hatters; it may, nevertheless, be merely a general impression. The diminution, it is said, is observed mostly among grooms and men of that class in the social scale. If this be really the case the change should be noticeable also among soldiers. The diminution is possibly more apparent than real, and may be traceable to alteration in the style of hair-cutting, or of wearing the hat. It has been suggested to me that men of the present generation have from birth smaller heads, dependent upon an alteration in the dimensions of the female pelvis, in consequence of modern fashion in dress. Of this opinion, however, I obtain no confirmation from eminent obstetricians of whom I have made inquiries. The statement then, as it stands, is wanting in explanation, and calls for further investigation. I may here quote the reply sent me by Prof. Flower to my question as to his opinion on the statement made by the hatters "that men's heads were smaller than they were twenty years ago":—

"Before drawing any important conclusion from such a statement it would be necessary to know much about the authority upon which it is made. Who, for instance, are the hatters that make it? Do all hatters concur in the same statement? Is it a mere general impression, or is it founded upon actual arithmetical data? Does it refer to any particular class of men, and does it refer to the same class of men? If it should be true, may it not arise from some change of fashion (if only founded upon the size of the hat, and not of the head) other even than the one you suggest, of hair being worn shorter—such as hats being worn more on the top of the head than formerly (in old-fashioned prints one sees the hat well down over the ears, which is certainly not the case now), or perhaps hats of the kind specified being now worn by a different (perhaps lower) class of the community, or by younger people? All these questions must be considered, and perhaps other sources of error eliminated which may not occur at first, before the statement can be accepted. If the evidence of the statement appears to bear investigation it would be well worth while following it up, as, if true, it would be one of the most remarkable facts with which I am acquainted, that in the space of twenty years a material diminution in the average size of the heads of the same population has taken place —a fact so contrary to all theory and to all experience."

For my own part I confess to some degree of scepticism as to the FACT, and should be glad of an explanation of this, probably only apparent, diminution in the size of men's heads.

Little Park, Enfield, October 26 W. B. KESTEVEN

The Evolution of the Palæozoic Vegetation

I AM pleased to have elicited the opinion of so distinguished an authority as Prof. Williamson upon Saporta and Marion's work, and his criticisms, even where antagonistic, will also, I am sure, be received by them with pleasure. Prof. Williamson holds views regarding the interpretation of some of the plant remains which are at variance with those held by most French geologists; but were the correctness of all his views conceded, I do not think Saporta and Marion's theory of the evolution of plants would thereby fall to the ground. A vast array of fact, which is not controverted, has been brought forward in a very able manner, and a connected and well-considered theory as to the nature of the modifications that have led through Cryptogams to Phanerogams is for the first time presented in a concise and lucid manner; and I think few will agree with the professor in deprecating such work because knowledge of the older floras is still incomplete. J. S. GARDNER

The Teaching of Practical Biology

IN the interesting introductory address of Prof. T. Jeffery Parker at Otago there is an omission which I am sure my friend would be the very first to wish to have rectified. In speaking of that remarkable development of the teaching of practical work in biological laboratories which will no doubt have a very considerable influence on the pursuit of this branch of science, Mr. Parker makes reference to the considerable services which have been rendered by Professors Huxley and Ray Lankester; but he forgot to say that one who, unfortunately, is no longer among us, provided for systematic teaching in practical work some time before Prof. Huxley was enabled to bring his wishes to fulfilment. The characteristics of this line of study were made known to the general zoological world in 1870, when Prof. Rolleston published his "Forms of Animal Life, being Outlines of Zoological Classification *based upon Anatomical Investigation* and illustrated by Descriptions of Specimens and of Figures." Prof. Rolleston's system was well enough shown in his preface to that work, where there occurs the following sentence, which I beg leave to quote as germane to this question:—"The distinctive character of the book consists in its attempting so to combine the concrete facts of zootomy with the outlines of systematic classification as to enable the student to put them for himself into their natural relations of foundation and superstructure."

The Igneous Rocks of Iceland

LAST year a friend and I rode round the north and west sides of Iceland, and from my observations then I cannot doubt that the conclusions to which Dr. J. Geikie has arrived concerning the south-west of the island apply equally to the more northerly parts. The glacier-scorings on the older lava were especially marked in a district unexplored except by a few Icelanders, and known as the Storisande or Big Sand. This desert lies to the north of Ball's Jokul and Lánge Jokul, and between Arnevatn and the River Blanda. As we crossed the undulating surface of the old lava, pale and ruddy in colour, the contrast was very striking where the black basalt seemed to rise from the plain in jagged cliffs up to the ice-field which caps these ranges. Where the sand was blown off this pale lava there were the lines of glaciation clearly engraved. The trend of the desert as a whole was towards the north, and the lines of glaciation ran north and south. In the Husavik district we saw, besides these two lavas, the lava of the present century, including that of 1875.

Replacing Flint Flakes

WITH reference to the replacing of flint flakes on Palæolithic implements it may be of interest to your correspondent, Mr. W. G. Smith (NATURE, vol. xxiv. p. 582), to learn that I have succeeded in building up a core out of Neolithic flakes. When searching the sandhills at Dundrum, Co. Down, last August, with my friend Mr. J. S. Hyland, I noticed a number of flakes of a similar colour lying on the slightly raised shingly beach on which the sandhills stand, at a point where the sand had apparently been recently blown away. Seeing from an imperfection in the stone that several fragments had formed part of the same flint, I collected all the pieces I could find, some of which were at a yard or two's distance from the rest. Without much trouble I was able the same evening to put them together, and have so fixed twenty-two flakes into position, forming about three-fourths

of the original pebble. The operator had first broken the pebble into two halves, and then chipped two-thirds of one half away in flakes, of which I found thirteen; the remainder of that half he threw down as useless. Of the other half I have nine flakes, and one is missing; the unbroken remainder is also gone. Perhaps the workman threw it away to a distance in disgust, as he does not seem to have got a single satisfactory flake out of the whole flint. The appearance of the half which I have almost complete is extremely like the illustration of the core made up out of a modern flint-knapper's flakes in Evans' "Stone Implements," except that the crowns of the flakes are triangular instead of quadrangular. There are the same small interstices between the crowns of the flakes, showing that the blow splinters off on each side of the bulb of percussion a small fragment, as well as the flake itself. This explains why the average concavity on the core is slightly less than the average convexity of the flake at the top of the bulb of percussion. F. ARCHER

Crosby, Liverpool

Climate of Atacama

SOME practical evidence as to climate has come forward at the shareholders' meetings of the northern Railways of Chile, the Coquimbo, Tongoy, and Carrizal and Cerro Blanco. In each of these districts torrential rains have occurred, which are all reported as unexampled. Long residents state that rain was formerly little known, and such was my observation in connection with the district. One reason why the weather is deserving of attention is that no change has taken place in the water-surface or vegetation. A similar change to rain in the Suez and Cairo district is attributed to the Suez Canal, but it is a matter worthy of consideration whether we are not really entering on a cycle of change. So far as Atacama is concerned, if at any former period there were rains, the conditions of habitation must have been different from those which have been so long considered to apply to the rainless district. HYDE CLARKE

PHYLLOXERA CONGRESS.—Dr. E. R. F. wishes to know where he can obtain a full report of the recent Phylloxera Congress at Bordeaux.

SCIENTIFIC INSTRUMENTS (J. S. MARSTON).—We cannot undertake to commend any particular instrument maker; you should get the lists of the leading makers, whose addresses you will find in our advertising columns.

HOLLOWAY COLLEGE.—So far as we understand this is not a charitable institution: Miss S. should write to the authorities at the College, Staines.

EFFECTS OF COLOURED GLASS (E. M.).—It is owing to the law you refer to.

THE AUTUMN SKY

I.

MANY and varied must ever be the regrets that attend the departure of summer days and summer pleasures; and their remembrance casts a lingering sadness even over the bright and beautiful hours that often alleviate the approach of sterner and gloomier seasons. Such impressions however are not shared alike by all. Few perhaps altogether escape their influence; but in some classes they are softened or even obliterated by the development of interests and pleasures of a very different description. Such is especially the case with the astronomical observer. The shortening of the twilight hours is to him as the withdrawing of a veil that obscured the minuter, yet not least interesting, features of the glorious scenes that he loves to explore; and he views with fresh pleasure the deepening tone of the background of unfathomable space, as the atmospheric illumination fades steadily away. We cannot indeed in our latitudes rival the transparent purity of the south, that gives such a magnificent depth to the aspect of the firmament, and throws out in such radiant brilliancy the host of heaven; yet even our autumnal skies are so great an advance upon the misty softness of the summer's night that the observer cannot but rejoice in their return.

These remarks are very obvious, not to say somewhat late in their application, when the sun has already advanced so far upon his downward way: yet they may not be entirely inappropriate when we are about to draw attention to some of the present characteristics of the sky. Much now in every direction invites the inquiring gaze, and an early hour challenges the opening of the observatory, or the arrangement of the telescope. Eye-pieces should be cleaned, adjustments rectified. Instruments of all kinds and sizes may be called into profitable and pleasant requisition—let the possessors only make the best of what they have. If we do not see more than we anticipate, though that may sometimes happen among the uncertainties of the English climate, yet we shall surely see enough to amaze us at the greatness of the Creator.

From its pre-eminent brightness, the planet Jupiter will naturally be the first object of attention. Belts we shall expect to find traversing his great broad disk, for they are very seldom absent; but there also we shall encounter a more unusual object, the ruddy patch, which has been sometimes described as vermilion, possibly from "personal equation," but which to most eyes exhibits a cinnamon or brick-red hue. There it has been, with scarcely any appreciable change, for the last three years[1]—a degree of permanence equalled, and even surpassed, by some dark spots in ancient days, but singularly contrasted with the general mutability of the markings of the disk. What is that spot? and where is it situated with regard to the real surface of the planet? Is it mere superficial colouring? but if so, of what material? Or is it an opening in the great mass of clouds—or what we call such—that is thought to envelope this colossal globe? But if so, how strange that its outline should have remained so steadily permanent. And in that case, as it is difficult to suppose it at the same level with those dark grey bands which have been ascribed to a similar absence of vapour, shall we place it above or below them? We might infer the former, if it is the case, as has been said, that it is more easily traced up to the limb than the dark belts; but the observation is delicate, and the effacing of the grey bands in that situation is not matter of universal consent. We might possibly conceive, on other grounds, admitting that the dark belts do indicate a deep clearing of vapour, that ruddy tints are caused by something at a higher level, because these are occasionally suffused over the whole equatorial zone and its markings, so as sometimes even to affect the general colour of the planet to the naked eye. The interposition of trees has prevented the writer hitherto from observation this year, but the accompanying sketch, taken 1879, November 12, with my 9⅓-inch

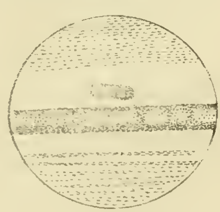

FIG. 1.

"With" mirror, may perhaps be of some interest in comparison with the observations of the present season.

The image, it will be noted, is telescopic, *i.e.* inverted.

[1] Traces of it may be detected in the Earl of Rosse's observations in 1873; but it seems to have been unnoticed in the interval.

The red spot was suspected to consist of two confluent masses, as well as to be somewhat inclined to the neighbouring belt; but the former idea, at least, not being confirmed by other observers, was probably owing to the inferior atmospheric conditions, which did not admit of a power much above 100. The central girdle consisted as usual of three divisions: the N. broadest and darkest, and of a cinnamon hue; the equatorial zone pale grey, with very feeble transverse interruptions, an indistinct continuation of the "portholes" so conspicuous some years previous; the S. band grey also, but deeper in tone. The N. hemisphere, beyond a bright region, had many faint grey stripes: towards the opposite pole was a feeble brownish shading; so that the colouring of the disk as a whole was, in heraldic language, "counterchanged." On other occasions very singular tints have been noted by eminent observers—yellow, full blue, and crimson; and the subject well deserves study, even though, as seems likely, that study should lead to little of a satisfactory nature.

Then there are other markings to be investigated on that great disk, both luminous and dusky, and that in another aspect, with a view to the determination of rotation; for, strange to say, it is found that some small dark specks travel more rapidly than other bright ones, and that the red spot moves slowest of all. And thus it is that the uncertainty in the axial velocity of that vast globe, first noticed by Cassini more than two centuries ago, is almost as far from being removed as ever; and, on the whole, one is tempted to question whether, after all, we have a single accurate idea, excepting that of mutability, concerning that enormous surface; and whether, if we could be transported there, we should not be surprised at the baselessness of all our conjectures. Certainly it may be said as to Jupiter, and not as to Jupiter only, that the recent advances in optical power and observing skill have only served to make more evident the thickness of the veil that obscures these objects in mystery. Analogy leads us a little way safely enough, but only to desert us before long. However, we must patiently watch and wonder.

Other matters, too, might be noted before we take our leave of that brilliant disk, so easy of investigation, so difficult to interpret. Why are the shadows cast on it by the satellites sometimes so black, at others so dim, or so abnormally small? Why, when a satellite passes behind the limb, is it sometimes neatly bisected by it, at others visible behind or through it, either from optical projection, as stars have been seen in front of the moon, or from the partial transparency of the edge of the globe? And then the satellites—they, too, have their anomalies in differences of apparent magnitude and brightness, due perhaps to variable obscurations of surface, but, if so, indicating conditions totally unlike that of our own satellite—the presence of considerable atmospheres, the possible want of coincidence between their periods of revolution and rotation—or even a superficial constitution as mutable and as hard of interpretation as that of the primary whom they obey.

We shall not remove our telescope far before a still more interesting and surprising object will present itself in Saturn, now especially suited for investigation, both as to altitude and the presentation of the ring. If there was much in Jupiter to perplex us, there is far more here; and it is rather mortifying to remark how little advance in knowledge has been made by the great increase, in recent years, of telescopic power. But little is ascertained now, beyond what was detected by the perfect vision of Dawes with his 6⅓-inch Merz object-glass, or the beautiful definition of the 15-inch achromatic, by the same maker, at Harvard College. A study, in fact, of the memoir by Bond and his associates, in the *Annals* of that college, vol. ii. part 1, published in 1857, would be the best preparation for an intelligent scrutiny of this planet. But not much beyond a general impression can be expected from ordinary telescopes. It will require considerable power, as well as light and sharpness, to detect Encke's subdivision of the outer ring (which, however, I caught in 1880 with my 9⅓-inch mirror), to trace any possible subdivisions of the inner ring, to ascertain whether, as Trouvelot thinks, the gauze veil is becoming less transparent in its outer portion, or to investigate those strange and puzzling outlines of the shadow of the ball on the rings, which, noted in part by others, have been recorded in detail in the Harvard memoir. A copy is here given of one, but not perhaps the most remarkable, of their diagrams.

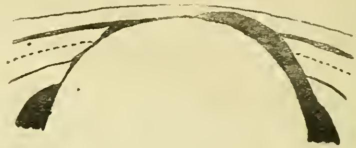

FIG. 2.

Such a contour could be only accounted for, if at all, by an amount of unequal thickness in the ring, which ought to be, but is not in the smallest degree, visible in the edgeways presentation. The success of Prof. Hall in detecting a bright spot of considerable permanency upon the ball encourages attention in that direction—especially as there are several previous records of such phenomena. To hunt for the smaller satellites with any but superior instruments would of course be waste of time, but it may be remarked that Enceladus has been seen by Ward with exceptionally keen sight and a 4·3 inch Wray object-glass, by Franks with 5 inch ditto, by Pratt with an 8·15 inch "With" mirror, and by myself with 9·33 inch. Mimas, the innermost, has been detected with a 7-inch achromatic by Wray. Meyer at Geneva has found it of late nearly as bright as Enceladus, and thinks it may be variable.

The morning skies at present are graced by Venus, not however a remarkable object in her gibbous phase; and Mars, who is coming rapidly round by his opposition to the evening. The smallness of his diameter, about 15″, is a great impediment, especially in the English sky, to the hope of success with his minor details, though it may be borne in mind that in the air of Milan, and with an admirably defining Merz object-glass of 7¼ inches, Schiaparelli has made many delicate observations on a scarcely larger diameter, and with exceptionally fine air has carried them down, strange as it may appear, to a diameter of only 6″.

The only other of the larger planets now visible is Neptune, easily picked up by means of an ephemeris, and distinguishable from a fixed star, even in a small telescope, by its dull and steady light. It demands, however, a large aperture for the bringing out and sharp definition of its pallid disk; in the latter respect the great achromatics at Rome (9·3 inch) and Bothkamp (11·5 inch) were unsuccessful, but I have seen it neatly terminated with Huggins's 15-inch object-glass. Its satellite, though glimpsed by Ward with a 4·3-inch achromatic, is far too difficult for ordinary vision or common apertures; I have seen it however plainly with the 15-inch just mentioned.

Vesta, though possibly visible with the naked eye, is a mere brilliant point of less than 1″ in the telescope.

Some notes on the autumnal constellations will be brought forward in a subsequent paper.

T. W. WEBB

(*To be continued.*)

METEOROLOGY OF BEN NEVIS

THE cairn on the top of Ben Nevis marks, as is well known, the highest spot in the British Islands, and when the question of high-level meteorological observations came to be seriously entertained some years ago, attention was drawn to this position as the best afforded in these islands for a first-class meteorological observatory which would form one of the more important members in the network of the high-level stations of the Continent. The advantages of the situation are enhanced by the consideration that the mountain rises directly from the level of the sea to a height of 4406 feet, and that its summit stands from 2000 to 3000 feet clear above the mountain ridge to westward which lies between it and the Atlantic. The mountain thus raises its head in the very midst of the west-south-westerly winds from the Atlantic, which exercise so preponderating an influence on the meteorology of Europe. Among the results from observations made at this elevated situation the more important to be looked for are those which relate to the greater movements of the atmosphere, particularly the upper currents in their relations to the cyclones and anti-cyclones of Europe, the data for the investigation of some of the laws regulating these movements being obtained by a comparison on the one hand of observations made on Ben Nevis with those made at the other high-level stations of Europe, and on the other with those made at lower levels, and published in the different Daily Weather Reports.

When therefore the Scottish Meteorological Society (last spring) accepted the handsome offer of Mr. Clement L. Wragge to ascend Ben Nevis every morning in time to make observations on the top at 9 a.m., every care and precaution was taken as regards the quality of the instruments procured, and in the arrangements made for their exposure and protection, so as to make the observations first-class, as far as this could be secured without constant residence on the top or the erection of continuously recording instruments. Further, as it is contemplated to build an observatory on the top, the arrangements regarding the instruments and their positions were carried out, so that all that will be required to complete the observatory is simply the erection of a suitable residence for the observers.

That Mr. Wragge possessed not only enthusiasm, but also strength of will, skill, and readiness of resource, was soon manifested. He met the Council of the Society in Edinburgh on May 26 and 27, was in Fort William on the following day, and on Tuesday, the 31st, fixed and secured the instruments in proper position on the top of the Ben, including a massively-built cairn for the reception of the barometer. On June 1, at 9 a.m., the observations were regularly begun, and have since been continued without the break of a single day up to the disastrous storm of October 14. This continuity, so extremely desirable in such a series of observations, was guaranteed by Mr. Wragge securing at the outset the services of a well-qualified assistant, whom he trained to the work, as well as a second assistant, whom he also trained, to meet any emergency that might arise.

The instruments are these:—A barometer inclosed in a cairn, 6½ feet high and 17 feet in circumference, which incloses a strong box fastened with lock and key, with a second door protecting the box from heavy rains and the gusts of wind which blow up the narrow gullies of the tremendous precipices, 1800 feet high, only a few paces off, and sweep over the instruments with terrific fury. A Stevenson's screen, with maximum, minimum, dry and wet-bulb thermometers, the bulbs of which are 4 feet above the mountain stone; the box opens to north, and also contains the ozone tests. The other instruments are a terrestrial minimum radiation thermometer, a solar maximum radiation thermometer, 4 feet high, and a rain-gauge, 8 inches in diameter, and its rim 1 foot high. Fig. 1 shows Stevenson's thermometer screen in elevation, erected on four stout posts, having angle-sloping stanchions, by which the box was securely and immovably fixed.

This arrangement continued till the end of July, when, as the tourist season was then setting in, a more effectual protection of the thermometers was necessary, so as to prevent the possible occurrence of any crowding of tourists immediately around the thermometers, or any other interference which might vitiate the readings made daily at so heavy an expenditure of time and trouble. In order to afford the required protection, Mr. Stevenson designed a strong wire cage, measuring five feet each way, the wire-netting being supported by strong iron rods continued downwards beyond the cage, and bent below at right angles. The horizontal projecting rods below are weighted with heavy blocks of stone, so as to secure complete stability to the structure. In the interior of the cage the Stevenson screen, with the thermometers and ozone tests, is placed, and firmly secured with supports.

Fig. 2 is a sketch of the station, kindly prepared by Mr. Wragge, which will explain, better than any verbal description could do, the arrangements which have been carried out with regard to the instruments, and also the remarkable character of the plateau at the top of Ben Nevis. A is the barometer cairn; B, the wire cage, with the thermometer screen seen inside; C, the solar maximum radiation thermometer, a black-bulb in vacuo, the terrestrial radiation thermometer being placed on one of the stones adjacent; D, the rain-gauge; and E, the hut, covered

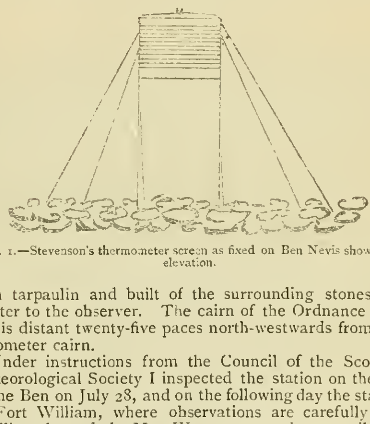

FIG. 1.—Stevenson's thermometer screen as fixed on Ben Nevis shown in elevation.

with tarpaulin and built of the surrounding stones for shelter to the observer. The cairn of the Ordnance Survey is distant twenty-five paces north-westwards from the barometer cairn.

Under instructions from the Council of the Scottish Meteorological Society I inspected the station on the top of the Ben on July 28, and on the following day the station at Fort William, where observations are carefully and intelligently made by Mrs. Wragge as nearly as possible at the same instant of time that observations are made at the top and at the different points on the outward and homeward journeys. We left Fort William about half-past five on Thursday morning, the party consisting of Mr. Wragge, Dr. Sanderson, the Society's honorary treasurer, Mr. R. C. Sanderson, and myself, as well as Mr. Wragge's Newfoundland dog, Renzo, that daily accompanies him in his ascents. The instruments are read at Fort William before starting, and the first observation on the journey is made at a peat bog, which was reached at 6.12 a.m., Mr. Wragge dismounting and reading his aneroid and sling thermometer, and noting the wind, clouds, and other observations of the weather. The lake was reached at 7.23 a.m., where the third set of observations were made, including the temperature of the water of the lake, which was 48°.3, being 3°.0 higher than that of the air. Here our ponies were left, and Mr. Wragge pushed on, in order to reach the top in time for the regular 9 a.m. observation, while we followed more at leisure.

Fig. [illegible].—The Summit of Ben Nevis.

The fourth set of observations were made at the spring, which is about 800 feet from the top, the temperature of the spring being 37°·4. Observations are again made at these same points on the homeward journey, which, together with the three at the top at 9, 9.30, and 10 a.m., make a daily series of ten observations, independently of those made at the same times by Mrs. Wragge at Fort William, and at other times in the afternoon and evening. In addition, extra observations are also made, such as when entering or emerging from the cloud-fog, when the wind suddenly changes in direction or force, &c., these being made from their important bearings on general atmospheric circulation. These observations, which are taken with scrupulous regularity, evince on the part of Mr. Wragge the most undaunted devotion to his work, particularly in consideration of the extreme discomfort they often entail, since to make them he must dismount not unfrequently in a piercingly cold storm of wind and rain.

The following are the observations made on July 28, at 9 a.m., by Mr. Wragge, and also those made at the same time by Mrs. Wragge at Fort William:—

	Ben Nevis, inches.	Fort William, inches.
Barometer at 32°	25·434	29·931
Aneroid	25·355	—
Max. Thermometer	36·8	54·0
Min. ,,	32·5	49·2
Dry bulb ,,	35·0	53·5
Wet bulb ,,	35·0	50·3
Solar max. ,,	94·0	—
Terres. min. ,,	32·2	—
	inch.	inch.
Rainfall	0·200	0·069
Wind, direction	South westerly	South westerly
,, force (0–12)	3 to 4	4
Cloud-fog (0–10)	10	9

We reached the summit shortly before eleven, the last 1000 feet of the ascent having been through a dense cloud-fog, which clung persistently to the mountain the whole time we were on it. We found the protecting wire cage in its position, having been placed there on the previous day, but the Stevenson screen was still in the position it had occupied since the observations began, and as is shown in Fig. 1. A reading of the instruments having been made, the workmen proceeded to remove the thermometer-box to its new position inside the wire cage, as represented in Fig. 2, and the party withdrew to the hut, which, though containing only one apartment, 8 feet by 4 feet, and its walls far from wind-tight, afforded a most welcome shelter from the bitterly cold masses of mingled fog, Scotch mist, and sleety drizzle which drifted across the mountain. A fire was quickly lighted in the middle of the hut with splinters of wood and balls of tow steeped in paraffin, the excessive dampness of everything rendering the use of paraffin indispensable. The inspection which followed showed that the full equipment of instruments were in excellent order and in excellent positions, and that the observations were made with a precision and a fidelity which left nothing to be desired.

At the time of our visit everything was drenched with wet. On opening the thermometer-box the whole inside presented the appearance of having been just lifted out of water, a drop hanging from the bulbs of the dry and other thermometers. Mr. Wragge informed us that during the fifty-one days preceding our visit the dry-bulb thermometer was found on opening the box to be without the drop hanging from it only on six occasions.

A noteworthy feature of the meteorology of Ben Nevis is the winds. Repeated instances were seen, during the ascent and descent, of a thin filmy fragment of mist suddenly appearing over one of the glens, which on being watched was observed slowly to ascend, lengthening and becoming denser as it rose, frequently assuming in time an appearance resembling the smoke rising from a burning mountain. On one occasion the whole of that

part of Glen Nevis seen from our position was clear of cloud and mist, but in a brief space of time, not exceeding five seconds, a dense mist suddenly filled the whole breadth of the glen, the upper limit of the cloud-fog being only a little lower than the level of our position. These facts point to ascensional movements in the atmosphere over Ben Nevis, which in all probability are caused by the temperature of the surface of the mountain being higher than that of the enveloping atmosphere at the same heights. These ascensional movements are disturbing influences on the winds prevailing on the Ben, but especially at the top, the result being that it is frequently difficult, if not impossible, to say what the true direction of the wind is, as it is found to blow from all points of the compass within the space of a few minutes.

In the accompanying sketch (Fig. 2), Mr. Wragge has given a faithful representation of the surface of the plateau of the summit. This plateau consists of about ninety acres, the difference of level between any two points of which does not exceed ten feet. It is throughout strewn to a depth of about four feet, with blocks of felstone lavas and volcanic agglomerates, nearly all tilted up to such a degree that the only mode of progression is over the sharp edges of the stones. These blocks are different from the rock of the mountain itself, the nearest rock resembling them being found in Glencoe, twelve miles distant. No soil is anywhere visible, the heavy rains doubtless having long ago washed it all down hill; indeed, except in small detached patches, the mountain is wholly bare of soil for the last 1500 feet of the ascent.

That the striking bareness of Ben Nevis is due to the excessive rains having washed away the soil, and not to the climate, is shown by the remarkably well-grown specimens of *Cerastium alpinum*, *C. trigynum*, *Saxifraga stellaris*, and *Alchemilla alpina*, which were found at heights closely approaching 4000 feet in situations which protected the soil from being carried away by the rains. In a small patch only 240 feet from the summit, I gathered a small grown specimen of *Saxifraga stellaris* in flower, and in the same patch there was growing a Carex, which however showed no flower. Excepting the above flowers and *Sagina saxatilis*, *Carex rigida*, *Luzula spicata*, and a single specimen of *Sibbaldia procumbens*, I did not notice any other flowering plants which a botanist would take the trouble to put into his vasculum. The scanty flora of Ben Nevis as regards the rarer species is thus in striking contrast to the rich floras of Ben Lawers and many others of our Scottish mountains, a circumstance which may perhaps possess some geological significance.

ALEXANDER BUCHAN

THE ELECTRIC TRAMWAY

ONE of the most interesting sights in connection with the Exhibition at Paris is the electrical tramway; it is a practical evidence of the great future in store for electricity as a motive power. From an article in *La Nature* we give some of the leading features of this recent application of electricity. In the case of a tramway the question is a complicated one, for the rails cannot be isolated, and they therefore cannot be used as

FIG. 1.—Siemens' Electric Tramway; Departure Station at the Place de la Concorde.

conductors. How then, in these conditions, is the motor of the carriage connected with the fixed generator placed in the Exhibition at the Palais de l'Industrie? This is the problem which MM. Boistel and Sappey, the engineers of Messrs. Siemens, have completely solved, after several fruitless attempts, which almost always precede successes of this kind. In the preliminary experiments made at the workshop in the Rue Picot, they made use, as conductors, of a brass tube electrically connected with the carriage by a traverser, the function of which we

shall explain; the wheels and rails will serve as the return wire. This system worked well at the *workshop.* In practice a special difficulty was encountered. The dirt sticking to the rails and felloes of the wheels formed a sort of crust so insulating as to prevent adequate communication with the earth. The increase of resistance produced by this interposition of finely conducting bodies was often sufficient to arrest the vehicle. The remedy was happily beside the evil, and a second conductor was established parallel with the first, in communication with the second pole of the generator, on which runs a second traverser, identical with the former. These two cars follow on their respective tubes the movements of the vehicle, and ensure a good and constant communication between the electrical generator and the motor. Fig. 1 represents the carriage and the station at the Place de la Concorde. At the height of the knife-board are seen the two conducting tubes supported at certain distances by posts, and in the intervals by iron wires, like the floor of a suspension bridge. The carriage is exactly the same as the ordinary tramway car. The motor is placed underneath the feet of the inside passengers; it is a Siemens dynamo-electric machine, with horizontal inductors similar to that which produces the current in the Palais de l'Industrie. The distance traversed is about 500 metres, and is accomplished in one minute. The work expended reaches 8 horse-power in the curved

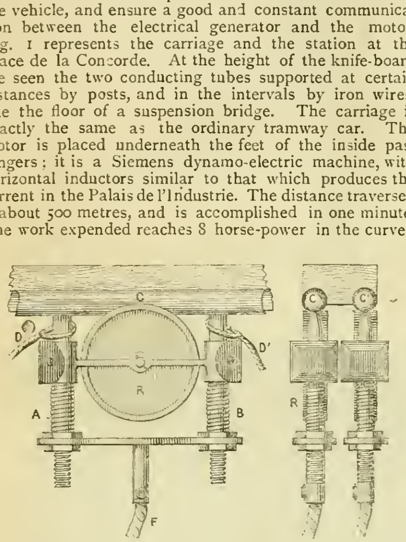

FIG. 2.—Traversers conducting the current to the carriage.

part; on a level straight run it does not exceed 3½ horse-power. The transmission of motion to the wheels is effected by means of a fall-chain. By a happy coincidence, which belongs to the very nature of the electric motor, the *static effort* is maximum when the motor is in repose. This renders the starting very easy, and no difficulty is met with from this point of view. To regulate the speed, resistances are introduced into the general circuit, which reduces the intensity of the current, and consequently the work of the motor; this operation is very simply effected by means of a lever placed at each end of the carriage. For stopping, the current is broken, and at the same time an ordinary brake is applied.

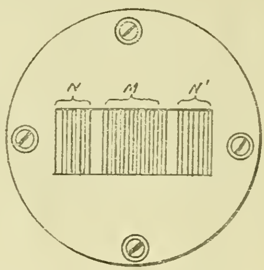
As to the mode of communication of the conductors with the carriage, we have said that it is effected by means of two identical traversers; it will suffice to describe one of them. Fig. 2 represents in detail one of these traversers. It is composed of a rectangular frame, bearing in its centre a wheel, of which the groove R is semi-cylindrical, and is applied against the exterior part of the conductor C, formed of a brass tube 22 millimetres in diameter and slit on its lower part along all its length to a breadth of about 1 millimetre. In this tube slides a cylindrical core of 12 centimetres in length, on which are fixed, at its extremities, two vertical shafts, A, B, which support the wheel or roller. Two springs supported on these vertical shafts press the wheel against the tube, and maintain an elastic contact between the tube and the wheel. The carriage may then be moved; the wheel runs against the tube, the core glides in the interior, without the communication ceasing to be, if not perfect, at least quite sufficient for the purpose. Only at times a few sparks are seen at the moment when the carriage passes the coupling of the tubes; these sparks are due to small instantaneous ruptures of the current which do not affect the regular working of the system. The experiment shows that the wear and tear scarcely affects the tube, and bears almost entirely on the core placed in the tube; but nothing is easier than to replace a core. The current reaches the machine by the copper conductor F. The traction of the carriage is effected by the cords D or D', according to the direction.

The electric railway of the Palais de l'Industrie presents the first practical solution of an electric traction in the case of a tramway. Of course it is easy to see how this application of electricity is capable of the greatest development, and that by modification of details the principle might be applied to railways.

THE BOLOMETER

AN instrument a thousand times more sensitive to radiant heat than the thermopile, and capable of indicating a change of temperature as minute as 1-100,000th of a single Centigrade degree, deserves the attention of the physicist. When to these qualifications it can be added that the new instrument is far more prompt in its action, and more reliable than the thermopile for the *quantitative* measure of radiation, then, indeed, no apology is needed for a detailed description. The instrument is termed by its discoverer, Prof. S. P. Langley, the *bolometer*, or *actinic balance*. The earliest design of the in-

FIG. 1.

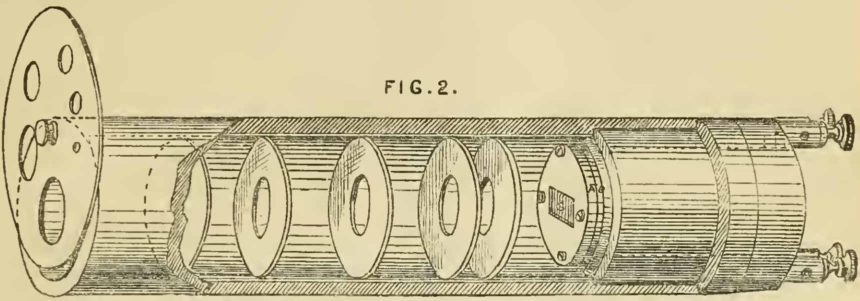


ventor was to have two strips of thin metal, virtually forming arms of a Wheatstone's bridge, placed side by side in as nearly as possible identical conditions as to environment, one only of them being exposed to radiation. Such radiation would slightly warm the strip and therefore alter its electric resistance, and the amount of this change would be indicated by the movement of the needle of the galvanometer placed in the middle circuit of the "bridge." For various reasons iron was eventually chosen as the material for the thin strips, as it combines the qualities of tenacity and laminability, with a greater sensitiveness in its electric resistance to temperature changes than either gold, platinum, or silver. Preliminary experiments made with a simple strip of iron in comparison with several delicate thermopiles showed the advantage of the new method of investigation A large Elliott thermopile of sixty-three pairs, a very sensitive thermopile of sixteen small pairs, and a delicate linear thermopile of seven pairs of elements were selected. The iron strip taken was 7 millims. long, ·177 millims. broad, and 0·004 millims

thick. Its resistance was 0·9 ohm. The three former instruments were one after the other connected with a short-coil mirror galvanometer of sufficient delicacy. The same galvanometer was used in the bridge, the three resistances used with the strip being respectively ·9, ·4, and ·4 ohm, and the total current employed being a little over half a weber. The result showed the sensitiveness of the three instruments and of the strip to heating by radiation to be respectively as 1, 4·1, 16·3, and 226·3.

The actual bolometer embodies the principle of the preliminary experiment with various additional refinements. Sheets of *steel* (palladium and platinum can also be used) are rolled out until of a thickness of from ·01 to ·002 of a millimetre is attained. Out of these sheets small gratings are cut or punched, having the individual bars about 1 millimetre wide and 1 centimetre long. Two systems of strips are arranged so that the current from a suitable battery divides itself, half passing through each, the interposed galvanometer showing no deflexion when the two currents are of equal strength. Fig. 1 shows the general arrangements of the gratings of strips. A rectangular opening is cut in a disk of ebonite of 3 centimetres

FIG. 2.

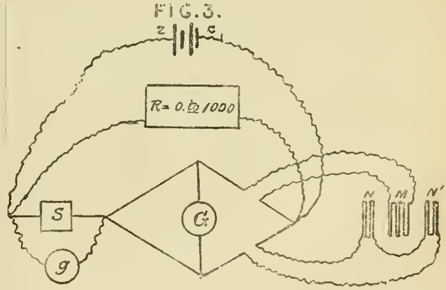


diameter. A second disk of the same size is clamped behind it, and between the two the gratings or systems of strips are fixed. That system which is to be exposed to radiation is placed in the centre of the rectangular opening at M. It consists of fifteen strips, eight of them being in front, and seven at a little distance behind. The second system is divided into two halves, N and N′, on each side of M, each half consisting of seven similar strips, four in front, three behind. Every joint is soldered, and the resistance of the fourteen strips in N N′ is made up equal to that of the fifteen strips in M by the interposition of a short wire in the circuit. M is placed in one arm of the bridge, and N N′ in the other, as indicated in the diagram of Fig. 3.

To protect the bolometer from air-currents, sudden changes of temperature, and from danger in handling, it is inclosed in a cylinder of ebonite lined with sheet copper. This is represented in Fig. 2, where the tube is drawn partly in section to display the interior. At the anterior end of the tube is a revolving diaphragm with suitable apertures. Within, a number of cardboard diaphragms or stops are placed, being retained in position by rings of ebonite tube between them. Behind these is the grating G of the bolometer fixed between the two disks of ebonite A and B. At the back there is a layer of solid non-conducting material, through which the conducting-wires pass to the two terminals. In the posterior end of the case are contained the resistance-wires by which to bring the two systems to equality; this being advisable because, if they are unequal at the beginning of the experiment, though they can be balanced by taking proportionally unequal resistances in the other arms of the bridge, according to the well-known law, any general rise of temperature will produce a *greater increment* of resistance in the system whose resistance is at first greater, producing a continuous "drift" in the galvanometer needle. Fig. 3 shows the connections of the bolometer and the bridge. A battery of one or more Daniell's cells, Z, C, provides a current the strength of which is controlled at will by changing the resistances in a box of coils, R, arranged as a shunt to the bridge-circuit. The working current is measured by a shunted galvanometer, *g*, and the two systems of strips M and N N′ of the bolometer are connected to their respective places in the bridge by four insulated wires twisted together and covered with flannel. A modification of the usual formula enables the change of resistance of M to be calculated from the currents observed in the galvanometer G.

The results of the new instrument are somewhat startling. A sunbeam one square centimetre in section will, according to Prof. Langley, warm one gramme of water 1° C. in one minute. It would therefore raise a sheet of water 1-500th of a millimetre thick, and 1-10th

FIG. 3.



of a square centimetre in area, $83\frac{1}{3}$° C. in one second, supposing all the heat to be retained. And as platinum has a specific heat of only ·032, the same sunbeam falling on a strip of platinum of these dimensions should, on a similar supposition, raise it in one second to 2603° C., a temperature sufficient to *melt* it! This result is, however, prevented by the re-radiation which the strip almost instantaneously exerts.

An examination of the heating effect of rays from different portions of the spectrum of solar radiations was made, but under conditions different from those of the measurements made by Müller, Herschel, and Tynda

These experimenters worked with spectra obtained by prisms of quartz, rock-salt, and other refractive substances. Prof. Langley used the far purer spectrum obtained by reflection from the surface of one of Rutherford's diffraction-gratings ruled on speculum-metal. This showed the result that *the heat-maximum* (of solar rays) *in a normal spectrum is not in the infra-red rays, but is at least as far up the visible spectrum as the orange near the D-line.* This result is so important that we append the figures. In the upper line are the wavelengths of rays in millimetres; in the lower the corresponding reduced galvanometer deflections.

λ	·00035	·0004	·0005	·0006	·0007	·0008	·0009	·0010	·0011
δ	12	55	207	256	198	129	80	58	41

[The H line in the violet has λ = ·00039; the D line in the orange has λ = ·00059; and the A line at the end of the visible red has λ = ·00076.]

We give the above figures as stated by Prof. Langley; but we cannot help remarking that if these were obtained by letting sunlight fall upon strips of *polished metal* they cannot be accepted offhand as a true representation of the facts of solar radiation, as they merely in that case indicate the position of the maximum of *the rays absorbed by the metal surface employed.* A blackened surface would without doubt tell a very different tale and show a maximum for other rays.

In conclusion it may be pointed out that the fundamental principle of the bolometer is identical with that of Siemens' electrical pyrometer, where also changes of temperature are measured by changes in the electric resistance of a conductor. But though the principle be identical the application is quite novel; and we must congratulate Prof. Langley on the skill and ingenuity with which he has applied an unpromising principle to the construction of this most interesting and most promising instrument of research.

S. P. T.

NOTES

THE announcement will be received with regret that Prof. Huxley, in consequence of the pressure of other duties, has been compelled to resign the Secretaryship of the Royal Society. It is believed that Prof. Michael Foster will probably be his successor.

SIR C. WYVILLE THOMSON has not yet resigned the chair of Natural History in Edinburgh University, though we regret to learn that he is likely to do so in a few days.

THE arrangements for the Crystal Palace Electrical Exhibition are progressing very satisfactorily. Major Flood Page has gone over to Paris to put himself in direct communication with the different administrations there and with the largest exhibitors. Applications for space have been very numerous, especially from English manufacturers. The Postmaster-General has signified his intention of sending all the apparatus now in Paris, and in addition there will be a considerable accession of modern apparatus in use in the Post Office Telegraph Department. The display will be essentially a display of the electric light. The whole of the building will be divided off and illuminated by the different inventors and manufacturers of lamps. The new Edison light will be shown in operation in the Concert Hall, and very great interest is evinced in the public display of this light. The effect produced by it in Paris was quite startling, and it is generally believed that Mr. Edison has solved the problem that he set himself, viz. to produce a light to supersede gas in our houses.

THE success of women in the late Honours Examinations of the University of London in Arts, Science, and Medicine was very remarkable. In the conjoint Honours Examination in Mathematics for candidates for the 1st B.A. and 1st B.Sc. Examinations Miss Charlotte A. Scott obtained the first place in the first class, with marks qualifying for an exhibition. In the 1st B.A. Honours Examination in English subjects Miss M. L. G. Petrie obtained a precisely similar position, whilst two other ladies, Misses C. A. J. Cl[illegible]ner and H. E. Clay, were also placed in the first class. In the 1st B.A. Honours Examination in German, Misses A. Page and H. H. Brown were placed in the first class, the former qualifying for a prize. Miss F. H. Prideaux actually carried off the supreme honours in Human Anatomy at the Honours Examination of the 1st M.B., being placed first in the first class, and being awarded the Gold Medal in Anatomy. In the Honours Examination in Materia Medica and Pharmaceutical Chemistry Mrs. M. A. D. Scharlieb attained a place in the first class.

THE first meeting of the one hundred and twenty-eighth session of the Society of Arts will be held on Wednesday, November 16, when the opening address will be delivered by Sir Frederick J. Bramwell, F.R.S., chairman of the Council. The following are among the papers which will be read during the session:—The American system of heating towns by steam, by Capt. Douglas Galton, C.B., F.R.S.; practical hints on the manufacture of gelatine emulsions and plates for photographic purposes, by W. K. Burton; stained glass windows, by Lewis Foreman Day; photometric standards, by Harold Dixon; telephonic communication, by Lieut.-Col. C. E. Webber; the causes and remedies of bad trade, by Walter R. Browne, M.A.; the native tribes of the Hudson's Bay Territories, by Dr. Rae, F.R.S.; the manufacture of ordnance, by Col. Maitland; some practical aspects of recent investigations in nitrification, by R. Warington; the production and use of gas for purposes of heating and motive power, by J. Emerson Dowson; gas for lighthouses, by John Wigham (illustrated by an exhibition of some of the gas flames and apparatus used in lighthouses); the relation of botanical science to ornamental art, by F. Edward Hulme, F.L.S., F.S.A.; the storage of electricity, by Prof. Silvanus Thompson, D.Sc.; the high-pressure steam-engine, by Loftus Perkins; the industrial resources of Ireland, by J. Philips Bevan; a new chemical compound, and its application to the preservation of food, by Prof. Barff, M.A.; the distribution of time by a system of pneumatic clocks, by J. A. Berly; tonnage measurement, by Admiral Sir R. Spencer Robinson, K.C.B., F.R.S.; tools and cutting edges, by D. A. Aird; the teaching of forestry, by Col. G. F. Pearson; the art of turning, by P. W. Hasluck. The usual short course of Juvenile Lectures, given during the Christmas holidays, will be by Mr. W. H. Preece, F.R.S., the subject being "Recent Wonders of Electricity." The following are the subjects of the courses of the Cantor lectures for the session just about to commence:—First course, on some of the industrial uses of the calcium compounds, by Thomas Bolas, F.C.S.; second course, on recent advances in photography, by Capt. Abney, R.E., F.R.S.; third course, on hydraulic machinery, by Prof. John Perry; fourth course, on book illustration, old and new, by J. Comyns Carr. In connection with Capt. Abney's lectures, it is intended to arrange for an exhibition of photographic apparatus, processes, &c. These lectures originated in 1863, with a bequest to the Society of Arts by the late Dr. Cantor. Since that date three or more courses have been given every session, each course dealing with some application of science or art to industry or manufactures.

WE understand that Mr. Donald McAlister, Fellow and Lecturer of St. John's College, Cambridge, has undertaken to prepare for Messrs. Macmillan and Co. an English edition of Prof. Ernst Ziegler's "Text-Book of General and Special Pathological Anatomy," which is on all hands regarded as the standard authority on its subject. The book will range with Dr. M. Foster's "Text-Book of Physiology," Gegenbaur's "Comparative Anatomy," and other works published by the same firm.

The eminent Italian geodesist, General Marquis J. Ricci, of Genoa, died at Novara on September 27, at the age of seventy years. The geodetic methods of Gauss, Bessel, and Baeyer were introduced into the geodetic work of Italy in great part through General Ricci, who was one of the original members and for long president of the Italian Commission for measuring the European degree.

It is stated that Mr. Robert Hart, C.B., Inspector-General of Chinese Customs, is getting a series of elementary science works translated into Chinese. Many foreign books have already been translated into that language, but they have been intended either for the higher officials or for the students at the free Government schools. Mr. Hart however intends, it is said, to endeavour to have the present translations circulated amongst all classes of the people; and his high official position would doubtless give him facilities for this purpose not possessed by any other foreign servant of the Chinese Government. It was, we believe, owing to the enlightened exertions of this gentleman that the *Tungwen*, or Foreign College of Peking, was extended so as to embrace a scientific curriculum, as well as to train interpreters in foreign languages, which was its original aim. From a recent calendar it appears that this institution now has nine foreign professors, besides numerous native tutors, and is attended by 102 students. One department of the College is devoted to the preparation of books for the diffusion of scientific and general knowledge. This is said to have been kept in view as a prominent object from the beginning. Among the scientific subjects taught we find chemistry, natural history, mathematics, animal physiology, and astronomy. Students who display conspicuous merit are entitled to the first step of the nine degrees of official rank. They are then appointed to the discharge of official functions in connection with some leading department of the Government, but they are required to continue their studies at the College as "resident graduates." A complete course lasts for eight years, the first three of which are given exclusively to foreign languages, and the remainder to the acquisition of scientific and general knowledge. Most of the students, moreover, as they are intended for a special service, receive a stipend varying with the length of their study, but which never exceeds about 3*l.* a month. This is certainly a good sign of the value attached by the rulers of China to Western knowledge; but everything does not present the same roseate hue in that country. We read that the line of telegraph erected from Soochow to Shanghai is being opposed by the agriculturists, who are placing all manner of obstacles in the way of the workmen employed. They pull up and destroy the poles, thinking that they act against the Fheng-shui, or geomantic influence, and are likely to lead to spiritual complications. Troops are stated to have been despatched to protect the line. Doubtless in time these deeply-rooted prejudices, which stand so much in the way of real internal improvements in China, will pass away; at present it must be acknowledged with regret that they are as living and active as ever. We notice that telephonic communication is about to be extensively employed in the large foreign settlement at Shanghai.

Lovers of Japanese porcelain will be glad to hear, on the authority of the Consul-General of the United States in Japan, that the modern productions will in time, if indeed they do not already, far surpass the older manufactures of Satsuma, Owari, Imari, and Kutani wares. The chief want of Japanese porcelain is regular symmetry in the pieces, and uniformity in a set or number of pieces. The absence of these is due, he says, to the fact, that machines or forms for moulding are not used, and the ovens are so defective that the heat is not evenly distributed. The native manufacturers are now manifesting much interest in the improvement of their wares. At one place the clay pits are said to have been worked for two thousand years or more, and the deposits seem scarcely more than scraped. Cobalt, used in colouring, is found in the same hills. The total value of the earthenware and porcelain exported from Japan to foreign countries during last year was valued at nearly one hundred thousand pounds sterling.

With the *Bilderschriften des Ostindischen Archipels und der Südsee*, Dr. A. B. Meyer begins the first part of a serial publication, which promises to be of great value to anthropologists. The distinguished curator of the Dresden Zoological Museum has undertaken, with the assistance of the Department of the Arts and Sciences, to issue a series of fac-similes, photographic or otherwise, of the most important objects in the extensive collection entrusted to his charge. This first part of the comprehensive project is devoted to the pictorial writings from Malaysia and the Pacific Islands, of which either the originals or exact copies are preserved in the Dresden Museum. As a detailed account of the series will be given on its completion, it will suffice here to state that the present number contains six folio photographic plates of the curious and hitherto undeciphered hieroglyphics or pictorial writings from North Celébes, the Pelew Islands and Easter Island. These are accompanied by eight folio pages of letterpress full of extremely interesting matter. For although no direct attempts are made at interpreting the texts, all previous essays of any value are collected, as well as such local myths or legends as may be likely to suggest a key to the interpretation of the writings. These are partly on wooden tablets, partly on prepared bast, partly also on the lintels and doorposts of the native houses that have been brought bodily to Europe. That they are all true writings, and not merely so much conventional ornamental work, a careful study of these plates will convince the most sceptical. Both the illustrations and the letterpress are produced in the sumptuous style characteristic of such publications in Germany.

The Committee on Photometric Studies appointed by the Board of Trade, have issued their report. Among other things they recommend that, for the determination of the illuminating power of coal gas, the use of the sperm candle should be discontinued, and that, for the future, Mr. Harcourt's air-gas flame, as defined in the appendix to the report, should be employed instead, as a means of affording with constancy the light of one average sperm candle. And in the event of any other mode of measuring the illuminating power of coal gas, such for instance as some modification of Messrs. Keates and Sugg's lamp or Mr. Methven's lamp being resorted to on account of its practical convenience, this other mode of measurement should be standardised, and from time to time checked, by comparison with Mr. Harcourt's air-gas flame, which should alone be taken as the official standard. The details of the experiments and evidence, on which the recommendations are based, are given in an appendix. These experiments were mostly conducted under the Committee's direction by Mr. Harold B. Dixon, the secretary to the Committee.

A Jamaica correspondent writes that Mr. Maxwell Hall, M.A., F.R.A.S., has succeeded, with some aid from the Local Government, in establishing a regular system of meteorological observations throughout the island, and a summary of these is published monthly in the *Jamaica Gazette*. A daily telegram is also sent round the island, giving results of readings at the chief stations, and any premonitory hints that may be considered necessary in view of telegraphic information from the United States signal stations at Key West and Cuba. Thus both shipping and agricultural interests are well prepared for any storms or hurricanes that may be expected. "Mr. Maxwell Hall's work," our correspondent writes, "though not yet fully recognised by the Government, is carried on in a most commendable spirit, and there is no doubt that when the benefits of regular and trustworthy meteorological observations are apparent,

and Mr. Maxwell Hall's numerous contributions to astronomical science are more fully appreciated, we shall have in Jamaica a properly equipped meteorological department, doing valuable work in this region, in which the distribution of hurricanes, and sometimes earthquakes, have so important a bearing on human life and the general prosperity of the island." A Weather Observatory, we learn from the *Jamaica Gleaner*, has been established by Mr. Hall at the Government Cinchona Plantations, at the residence of Mr. Morris, director of the Botanical Department, who has undertaken voluntarily to give it personal and daily attention. This observatory is at a height of 4900 feet.

SPARROWS have multiplied to such an alarming extent in South Australia that a Commission appointed by the Government have sent in a report recommending means to be taken for their destruction, and rewards to be given for heads or eggs.

MR. J. H. WILLMORE, of Queenwood College, near Stockbridge, Hants, writes under date November 1: "A 'Storm-Petrel was found not far from here on Sunday week. The little bird was lying on its back on the top of a hedge, and had evidently been dead some days. On opening it one side of its body was found to be black, as if it had died from a blow. I imagine the very rough weather had driven it inland, and it had come into contact with one of the trees close by. These birds are, I believe, very rarely found so far inland, and, so far as I can learn, this is the first instance in this neighbourhood."

MR. PARK HARRISON has published, through Quaritch, an interesting account of an incised slate and various other objects discovered in an old structure at Towyn, Merionethshire. The slate is covered with many curious figures, evidently cut by the hand of man; and these Mr. Harrison endeavours to interpret. There are numerous illustrations, including an autotype reproduction of the slate itself and another with only the figures clearly brought out.

SINCE 1869 the Otago (New Zealand) Acclimatisation Society has, we learn from the *Colonies and India*, liberated 157,041 young trout, and has sent 135,110 trout ova to various parts of Otago. Since 1874 it has liberated 34,900 salmon fry, and in 1879 and 1880 it liberated 790 perch and 60 tench. Young American "White-fish" (*Coregonus albus*), let loose in the lakes in the Rotorua district about two years ago, have been recently met with by the natives; but as soon as it was discovered what the fish were they were returned to the water. The natives are delighted at the discovery. The Auckland Society has, through want of support, been compelled to sell by auction its stock of animals and plants.

THE Brighton Health Congress and a "Domestic and Scientific Exhibition" will be held in the Pavilion Dome and Museum in the second week of next month. The president of the Congress is the Earl of Chichester, and the president of the Exhibition is Dr. B. W. Richardson.

M. LOEWY, sub-director of the National Observatory of Paris, has been appointed by the Government to report on the state of French provincial observatories, which have recently received a credit of 4000*l*. from the French Parliament. These establishments are five in number:—(1) Marseilles, directed by M. Stephan, with MM. Borelly and Coggia and two computers, has a credit of 1250*l*. The principal work is observation of nebulæ by Stephan, revision of Rumker's catalogue, discovery of comets and small planets, study of intra-Mercurial planets by Borelly, determinations by the Gauss method of absolute magnetic declination, &c. (2) Toulouse Observatory, directed by Baillaud, with a budget of 880*l*. and a municipal subvention of 200*l*. for printing the observations. A magnetic pavilion has been built with compass constructed by Brümer. The principal work is the observation of sun-spots, cataloguing variable stars, and observation of August meteors; not less than 1300 were tabulated on the last occasion of their appearance. (3) Bordeaux, directed by Rayet, with a credit of 1200*l*. The regular work has not yet begun, but observations have been made on comets and the red spot on Jupiter. (4) Lyons, directed by André, the credit given by the Government being 800*l*.; the amount of subvention paid by the city is not stated. The principal feature of this observatory is its connection with three meteorological stations situated in the vicinity—one at Tête d'Or, the second at Mont Verdun, and the third at Ampius. The regular astronomical work has not yet been begun. (5) Algiers, directed by M. Trepied, has a credit of 1500*l*. from the Government. The principal work has been the observation of Jupiter's satellites.

A VETERAN watchmaker at Vouvry, Switzerland, claims to have invented a process by which watches will run for years without winding up. A sealed box containing two watches intrusted to the municipal authorities on January 19, 1879, has just been opened, and the watches were found going.

THE Council of the Institute of Civil Engineers have issued their usual lists of subjects for papers in connection with the various premiums which they award. A copy can be obtained at the Institute, 25, Great George Street, Westminster.

M. HANS H. REUSCH describes in the Danish *Naturen* (No. 9, 1881), a new find of Silurian formation on the western coast of Norway, at Ulven, two miles south of Bergen. The fjeld consists here of conglomerate, sandstone, and clay slate, with concretions of limestone which contain remains of Silurian corals, casts of graptolites, and trilobites. The formation is equivalent to that of Central Norway.

SEVERAL further experiments have taken place at the Paris Opera in electric lighting. The success has been very great for the incandescent light in the hall, and for the Brush system on the staircase. For the first time gas has been wholly suppressed in several parts of the house.

IN the *Times* of October 29 is a very interesting account of the present condition of the St. Gothard Tunnel, from a correspondent who went through it.

IN *Bulletin* vol. vi. No. 2 of the United States Geological and Geographical Survey, Mr. S. H. Scudder gives an analysis of the insect remains found in the rich Tertiary Lake Basin at Florissart, Colorado, in anticipation of his forthcoming memoir on the subject.

MR. LATIMER CLARK has printed, in the form of a pamphlet a list of the rare and curious books relating to Electricity and Magnetism which he exhibits at the Paris Exhibition.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. G. Aldridge; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. Francis B. Norcliffe; a Tarantula Spider (*Mygale*, sp. inc.), a Millipede (*Julus*, sp. inc.) from Pernambuco, presented by Mr. Charles C. Craven; a Smooth-headed Capuchin (*Cebus monachus* ♂) from South America, a Richardson's Skua (*Stercorarius crepidatus*), British, four Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, deposited; a Hooded Crow (*Corvus cornix*), a Common Rook (*Corvus frugilegus*), two Grey Plovers (*Squatarola helvetica*), a Ruff (*Machetes pugnax*), a Bar-tailed Godwit (*Limosa lapponica*), British, a Green-cheeked Amazon (*Chrysotis viridigenalis*) from Columbia, a Finsch's Amazon (*Chrysotis finschi*) from Mexico, purchased; four —— Finches (*Coryphospingus cristatus* ♂ ♂ ♀ ♀) from Bolivia, on approval.

OUR ASTRONOMICAL COLUMN

THE BINARY STAR γ VIRGINIS.—Dr. Doberck has recently determined the elements of this star from all the measures available up to the spring of the present year. He gives two orbits, the second of which represents the measures about the periastron-passage somewhat better than the first, but otherwise has no material advantage over it. Dr. Doberck points out that the part of the orbit most interesting to examine was described between the years 1839 and 1847, when the angle of position, after being very oblique, passed quickly through zero, without very much alteration of distance. He finds that the correction required by the angles observed by Dawes, who used a prism for the purpose of keeping the images of the stars apparently in the great circle passing through the zenith, did not much change; those of M. Otto Struve altered in a most pronounced manner; but he adds, "it is quite natural that the errors should be rather large in the case of these stars, which for most observers were at no great distance from the southern horizon, and which, in most telescopes, appear as large disks, at least when the state of the atmosphere is not exceptionally favourable." Dr. Doberck gives a separate comparison with the observations of the Pulkowa astronomer from 1840 to 1874 both as uncorrected and with the corrections in the "Observations de Poulkowa," vol. ix.; he finds that "the observed distances are improved by the corrections, except before 1843, when no corrections ought to be applied," and this is apparent from his investigations on the elements of other double-stars: the angles also are confirmatory, but would be better without the corrections as late as 1853. We subjoin Dr. Doberck's second orbit, and for the sake of comparison the orbit deduced by Thiele, after a very full discussion of the measures up to the year 1865, taken from his treatise published at Copenhagen in 1866.

	Doberck.	Thiele.
Periastron passage	1836·450	1836·685
Node	46° 0′	35° 35′
Periastron from node on orbit (λ)	273 55	283 44
Inclination	33 9	35 6
Eccentricity	0·89040	0·89575
Semi-axis major	3″·94	3″·97
Period of revolution	179·65 years	185·01 years.

We have added 180° to Dr. Doberck's element (λ), to accord with the angle as it was expressed by Dawes and most other observers until within a recent period, but there appears to be slight variation in the brightness of one of the components, as will be seen from an inspection of M. Otto Struve's observations in the Pulkowa volume referred to above.

THE TRANSIT OF MERCURY, NOVEMBER 8.—This is a phenomenon of which we must look for particulars from observers in Australia: it will be wholly invisible in Europe, the conjunction in R.A. taking place at 0h. 38m. a.m. Greenwich time. At the next transit on the morning of May 10, 1891, the egress only will be observable at Greenwich, the sun rising at 4h. 19m., and the last external contact occurring at 4h. 50m. The conditions are reversed in the following transit on November 10, 1894; the first external contact will take place at 3h. 55m. p.m., and the sun's upper limb will be in the horizon at 4h. 18m. This will be the last transit of Mercury in the present century.

COMET 1881 *f* (DENNING).—M. Schulhof of Paris has found elliptical elements for this comet: the period assigned is 7¾ years, but is yet uncertain. A near approach to the orbit of the planet Jupiter is shown by M. Schulhof's ellipse in heliocentric longitude 219°·7, at which point the distance is only 0·18 of the earth's mean distance from the sun.

GEOGRAPHICAL NOTES

MR. JAMES JACKSON, "Archiviste-Bibliothécaire" of the Paris Geographical Society, has published, in a volume of 340 pages, a "Liste Provisoire de Bibliographies Géographiques Spéciales." The list was undertaken at the instance of the Society, and was printed in some haste, we believe, for the recent Venice Congress. But when we remember that the list is only a bibliographical one, a list of lists, in fact, the accumulation of geographical literature is almost appalling. It bears evidence of extensive and careful research, though the author admits that it is by no means exhaustive. Mr. Jackson recently visited the United States to search the libraries there, and the result is a work invaluable to all students of geography. He has wisely devoted comparatively small space to Europe, because, as he states, the works relating to the countries of that continent are well known and easily accessible. Mr. Jackson gives not only bibliographies proper, but references to works on travel and geography, and to periodicals, journals, and transactions, which contain special lists. The divisions of the list are:—Europe, Asia, Africa, America, Oceania, Polar regions, Oceans and Hydrography, Peoples and Nations, Voyages, Travellers, and Geographers, and Generalities. By means of the arrangement under each division the methodical table of contents, the index to authors and periodical publications, the work is rendered easily consultable. It reflects the greatest credit on Mr. Jackson's industry, and on the enterprise of the Paris Society.

THE only new paper in the Geographical Society's *Proceedings* is Mr. William Beardall's on his exploration of the Rufiji River under the orders of the Sultan of Zanzibar, which lasted from December 8, 1880, till February 19, 1881, and, we believe, was undertaken mainly at the suggestion of Sir John Kirk. A sketch map of the river accompanies the paper, on which the portion above Mpembeno, almost to E. long. 37°, is given from Mr. Beardall's surveys. The geographical notes furnish some particulars respecting the Italian Antarctic Expedition, Mr. Joseph Thomson's recent exploration of the Rovuma district of East Africa, and the American Missionary Expedition to the Bihé plateau in West Africa. There are obituary notices of the Visconde Duprat, the Rev. F. W. Holland, Major S. Anderson, R.E., Sir Vincent Eyre, and Col. T. G. Glover, all of whom had rendered more or less important services to geography.

WRITING on a new map of the Dutch East Indies, about to be published at the Hague, the *Annales de l'extrême Orient* for October mentions that, besides its scientific value, this map is interesting from the adventures which have attended its production. The four stones which together form the lithograph were engraved for the most part in Java, the orography and the names alone remaining to be done in Europe. They were carefully packed and despatched to Holland by one of the Dutch mail steamers, but the latter unfortunately was wrecked, and the stones sank to the bottom of the sea. After much trouble the huge cases containing them were raised, and ultimately arrived at their destination. The new map is on a scale of 1 to 500,000, and is in three colours: the mountains in bistre, the seas, lakes, &c., blue, and the remainder in black. The leaves measure 218 centimetres by 78.

IN an "occasional note" on Monday, the *Pall Mall Gazette* predicts a miscellaneous Arctic meeting for the opening of the Geographical Society's session on November 14. If this should prove correct, it is to be hoped that Capt. Gray may be induced to give some verbal information on his discovery that the Polar-pack was this summer six degrees nearer the shores of Europe than in 1879. Though the note in question is, no doubt, to some extent inspired, we believe the evening's programme is by no means finally decided upon. The subject on which the president, Lord Aberdare, in his address would most naturally dilate, would be his recent visit to Venice, in which case we may hope for an intelligent and intelligible account of the proceedings of the Geographical Congress. Hitherto we have heard of little but some effusive speeches and the showering of diplomas and medals on the foreign societies and individuals who took the trouble to send articles to the Exhibition.

WITH reference to the report that Mr. Gordon-Bennett is about to visit Dundee in order to purchase a whaler to be sent in search of the *Jeannette*, it is probable that this new expedition is the one which Lieut. Hovgaard, of the *Vega*, has volunteered to lead.

CAPT. MEYER, of the German schooner *Phœnix*, at Callao, from San José de Guatemala, reports having discovered a new island. According to advices received by the West India Mail it is in lat. 7° 48′ S., long. 83° 48′ W., lying about 188 miles from Punta Aguja, which is the nearest land. The island appeared of volcanic origin, not being over fifty feet above the sea in its highest part. It is a mile long, and about the same width, and Her Majesty's ship *Kingfisher* and the United States vessel *Alaska* have been despatched to examine it. The Chilian transport *Chile* has also been ordered to pay it a visit during a trip she is now making to the North.

MR. JOSEPH THOMSON has returned to Zanzibar from a three months' exploration of the Loende tributary of the Rovuma

River. Not a trace of coal was found along the whole course of the river, though it was reported by the natives to be seen in abundance protruding on the river banks. The whole country is thickly covered with wood. Mr. Thomson contemplates setting out on his second expedition during the present month. He intends to visit the little-known region between the sea and Mount Kilimanjaro, extending from Melinda on the north to Pangani on the south. Mr. Thomson hopes to make important discoveries in geology and botany.

A PRETTY full account of the proceedings of the recent International Geographical Congress at Venice will be found in the new *Bollettino* (for August) of the Italian Geographical Society, which reports in full the papers on the question of oscillations on the coast of Italy. It contains besides a map showing the various arcs of meridian and parallels that have been measured all over the world, and a map of Europe showing the present state of the various trigonometrical surveys in that continent. Russia, Turkey, and Greece are almost blank, and the Scandinavian peninsula is far behind; the other countries are shown covered with triangles.

LUNAR DISTURBANCE OF GRAVITY[1]

IN November, 1878, Sir William Thomson suggested to Mr. G. H. Darwin that he should investigate, experimentally, the lunar disturbance of gravity and the question of the tidal yielding of the solid earth. This Committee of the British Association was subsequently reappointed, and the authors' names were added to the list of its members. In May, 1879, the authors visited Sir William Thomson at Glasgow, and there saw an instrument which, although roughly put together, he believed to contain the principle by which success might perhaps be attained. The instrument was erected in the physical laboratory of the University of Glasgow. The following are the rough details:—

A solid lead cylinder, weighing perhaps a pound or two, was suspended by a fine brass wire, about five feet in length, from the centre of the lintel or cross-beam of the solid stone gallows which is erected there for the purpose of pendulum experiments. A spike projected a little way out of the bottom of the cylindrical weight; a single silk fibre, several inches in length, was cemented to this spike, and the other end of the fibre was cemented to the edge of an ordinary galvanometer-mirror. A second silk fibre, of equal length, was cemented to the edge of the mirror, at a point near to the attachment of the former fibre. The other end of this second fibre was then attached to a support, which was connected with the base of the stone gallows. The support was so placed that it stood very near to the spike at the bottom of the pendulum, and the mirror thus hung by the bifilar suspension of two silks, which stood exceedingly near to one another in their upper parts.

It is obvious that a small displacement of the pendulum, in a direction perpendicular to the two silks, will cause the mirror to turn about a vertical axis.

A lamp and slit were arranged, as in a galvanometer, for exhibiting the movement of the mirror by means of the beam of light reflected from the mirror. It was found to be in incessant movement, of so irregular a character that it was hardly possible to localise the mean position of the spot of light on the screen, within five or six inches. On returning to the instrument after several hours, the observer frequently found that the light had wandered to quite a different part of the room, and it was sometimes necessary to search through nearly a semicircle before finding it again. The cause of this extreme irregularity of the movement of the pendulum was obscure; and as Sir William Thomson was of opinion that the instrument was well worthy of careful study, the authors determined to undertake a series of experiments at the Cavendish Laboratory at Cambridge.

Accordingly throughout 1880 they proceeded to make experiments with an instrument which involved the principle above explained. Several modifications of some importance were introduced. The pendulum was hung in fluid, in order to quickly destroy the oscillations generated by local tremors, and, being suspended by two wires, it was only free to oscillate in one direction, namely, the meridian. There was also introduced an apparatus, which we have not space to explain, by which a known very small horizontal thrust might be applied to the pendulum. By means of this the actual displacements of the pendulum were determinable from the observed displacements of the spot of light on the screen.

The image on the screen was found to be in a state of continual agitation of an irregular character, so that it was not possible to take a reading with very great accuracy. But as the pendulum was hung in fluid, the agitation was not nearly so great as it had been in the instrument at Glasgow.

The observers also found that the pendulum was subject to a diurnal oscillation, and that it stood furthest north towards 6 p.m., and furthest south towards 6 a.m. Superposed on this motion was a gradual change of the mean diurnal position, for during two months the pendulum moved northwards.

The instrument was found to exhibit the flexure of the stone piers of the gallows, even when the force employed was only a slight pressure with one finger. Water poured on the ground round the basement of the stone gallows tilted the whole structure over, and very small changes of temperature in the stone piers were found to give distinct effects. It was concluded that 1 foot of displacement in the spot of light on the scale corresponded with 1″ of change in the direction of the plumb-line with reference to the base of the gallows.

From these experiments the authors concluded that the instrument was susceptible of all the delicacy requisite, but that the mode of suspension was unsatisfactory.

Accordingly in 1881 they proceeded to erect a new instrument in which the support for the pendulum was a copper tube, which itself formed the envelope for containing the fluid in which the pendulum was suspended. The whole apparatus was immersed in a large mass of water, and the observations were taken from outside of the room by means of a telescope. The unsteadiness of the image was diminished, probably on account of the precautions taken against inequalities of temperature in various parts of the instrument, and because the pendulum was hung in a very confined space. The accuracy with which readings could be taken was thus increased.

Similar diurnal oscillations of the pendulum were again observed, and a similar slow change in the mean diurnal position. The authors therefore concluded that these changes are a real phenomenon, and do not depend upon changes of temperature in the instrument itself.

They also noted that there are periods lasting for several days in which the pendulum is in a state of continual agitation, so that the readings taken at a few seconds apart do not agree *inter se*, and that there are other periods of abnormal quiescence. These periods do not seem intimately connected with the external meteorological conditions, at least as far as the experiments have been hitherto carried.

The pendulum was found to be practically insensible to the effect of local tremors, such as are produced by hitting the stone support or stamping on the ground in the immediate neighbourhood of the instrument. But it was extraordinarily sensitive to steady forces. If a force be applied at a point on the floor a dimple is produced in consequence of the elastic yielding of the soil, and any object on the floor is slightly tilted towards the point where the force is applied. Now when a person stood in the room at sixteen feet away from the instrument, and again at seventeen feet, the difference was rendered distinctly evident between the amounts of inclination towards the point of pressure of the stone basement supporting the pendulum in the two cases.

Although no great pains had been taken to render the instrument as sensitive as possible, it was found that an alteration of the plumb-line through 1-100th of a second of arc was distinctly measurable.

The second part of the paper contains an account of the work of some of the previous observers on the same subject.

M. Zöllner's instrument, the "horizontal pendulum," is described. It does not appear that any extensive series of observations have been made with it.

An account of M. d'Abbadie's work is next given. He made his observations by means of reflections from a pool of mercury, and the site of his experiments was at Abbadia, near Hendaye, in the south of France. He found that there were periods of agitation and of quiescence in the mercury, apparently without reference to any perceptible external causes. There were also gradual changes of level extending over several months, and the

[1] Report of the Committee, consisting of Mr. G. H. Darwin, Prof. Sir William Thomson, Prof. Tait, Prof. Grant, Dr. Siemens, Prof. Purser, Prof. G. Forbes, and Mr. Horace Darwin, appointed for the Measurement of the Lunar Disturbance of Gravity. Account of experiments by G. H. Darwin and H. Darwin, read at the British Association, York, September 1881.

experience of several years showed that there was something like an annual inequality of level. There were sometimes changes through 2″ or 3″ which took place in a few hours.

At Geneva M. Plantamour has been making observations concerning variations of the plumb-line, by means of delicate levels, and has arrived at results in general accordance with those of M. d'Abbadie.

The experiments of the authors present a general confirmation of these conclusions, and show that the earth's surface is in a state of continual movement.

With reference to this continual oscillation the authors adduce an experiment which was commenced about three and a half years ago by Mr. Horace Darwin at Down, in Kent. The experiment was undertaken in connection with Mr. Darwin's investigation of the geological activity of earthworms. There are two stout metal rods, one of iron and the other of copper. The ends were sharpened, and they were hammered down vertically about eight feet deep into the soil, and they are in contact with one another, or nearly so. The ends were then cut off about three inches above the ground.

A stone was obtained like a small grindstone, with a circular hole in the middle. This stone was laid on the ground with the two metal rods appearing through the hole. An arrangement with a micrometer screw enables the observer to take contact measurements of the position of the upper surface of the stone with regard to the rods. The stone has, on the whole, always continued to fall, but the general descent can only be gathered from observations taken at many months apart, for it is found to be in a state of continual vertical oscillation.

The measurements are so delicate that the raising of the stone produced by one or two cans full of water poured on the ground can easily be perceived. The effect of frost and the wet season combined is strongly marked, for on January 23, 1881, the stone was 4·12 mm. higher than it had been on September 7, 1880. The prolonged drought of the present summer has had a great effect, for between May 8 and June 29 the stone sank through 5·79 mm.

The changes produced in the height of the stone are, of course, entirely due to superficial causes; but the amounts of the oscillations are certainly surprising, and although the basements of astronomical instruments may be very deep, they cannot entirely escape from similar oscillations.

The last part of the paper contains a discussion of the present aspects of the question, and a criticism of the various forms of instrument which have been used hitherto for the detection of small variations in the position of the plumb-line.

The authors suggest that greater precautions should be taken in the protection of the piers of transit instruments from changes of temperature, and in the drainage of the soil round the basements of the piers; they also draw attention to the disturbing effect of the weight of the observer's body. They express a hope that systematic observations of changes of level may be undertaken at a number of observatories by some instrument analogous to that with which they are working. They are still prosecuting their experiments, and they are in hopes of being able to reduce their instrument to a convenient form, so that it may not be difficult to transport or to erect.

In conclusion they state that they have no hope of being able to observe the lunar attraction in the present site of observation, but they think it possible that they may devise a portable instrument which shall be amply sensitive enough for such a purpose, if the bottom of a deep mine should be found to give a sufficiently invariable support for the instrument.

AN ERROR IN THE COMMONLY ACCEPTED THEORY OF CHEMISTRY

AT a public meeting of the University College Chemical and Physical Society Prof. A. W. Williamson, F.R.S., gave an address on "An Error in the Commonly Accepted Theory of Chemistry."

He began by saying that he had been frequently struck by the fact that two theories believed at one time to be conflicting had often been shown by the progress of study to be both true. As an instance in point he took the rival theories, one of which represented molecules as constituted after the pattern of three or four types, while the other viewed them as containing complex groups called radicles

There was at one time opposition between those who made use of atomic weights and those who employed equivalent weights; the most important step that has of late been taken is the introduction of the notion of equivalence into the atomic theory; an inspection of the series HCl, H_2O, H_3N, H_4C showed that the atom of chlorine has a different value to that of oxygen, nitrogen, or carbon; thus ammonia may be viewed as being formed by replacing three atoms of chlorine in three molecules of hydric chloride by one atom of nitrogen. Thus nitrogen was said to be trivalent or a triad, and other elements, such as phosphorus, boron, &c., were found to resemble it in this respect; oxygen was called a dyad, and it was found that sulphur, calcium, &c., might also be classed as divalent; in short every element might be placed in one or other of the groups, monad, dyad, triad, &c. That an element can belong to one only of these groups was the view still held by one distinguished chemist, who, for instance, said that nitrogen was trivalent only, and that in sal-ammoniac it was not pentavalent, but that the body in question was a molecular compound of two chemical compounds, ammonia and hydric chloride.

He (Prof. Williamson) thought this was little else than a return to Berzelius' mode of representing compounds, though it was open to an objection from which the theory of the Swedish chemist was free; for Berzelius said that the force which united the two molecules that made up the compound molecule was identical with that which held together the atoms of the constituent molecules, the force being in each case electrical; whereas Prof. Kekulé assumes the forces in the two cases to differ, the one being molecular, and the other chemical.

Now as long as we knew neither of these forces, he (Prof. Williamson) thought it hazardous to assert that there was a difference between them. A study of the evolution of heat in chemical processes threw some light on the subject; Berthelot and Thomsen had shown that when you placed a number of substances within the influence of one another, that reaction or decomposition took place which could evolve the most heat, and we must take into account not merely the heat given out by what we considered the purely chemical process, but also that due to the passage of the product from one state of aggregation to another—from the liquid to the solid state when a precipitate was formed.

Thus the chemical process was determined by the heat due to the chemical reaction plus that due to change of physical condition; and this indicated an identity between chemical and physical force. We might learn the same lesson from Deville's truly remarkable researches on dissociation or strictly reversible decompositions. Thus calcic carbonate was decomposed by heat into lime and carbonic acid, but no sooner was the temperature sufficiently lowered than the two recombined; so, when water was heated, the molecules were separated and formed steam, but on lowering the temperature they recombined to produce water. Ice, water, and steam had in many respects different properties—differences in specific gravity, specific heat, refractive power, &c., quite analogous to those which were found between different chemical compounds.

We had therefore no grounds for assuming a difference between chemical and physical force; Kekulé's theory that an atom can have one, and only one, atomic value was no longer tenable, for it involved the assumption of molecular compounds. The theory commonly in vogue was that atoms vary in their value within certain narrow limits; that nitrogen, for instance, was either trivalent or pentavalent. It had even been asserted that the combining power of an atom was independent of the nature of the elements with which it combined; in the words of a very distinguished chemist, "No matter what the character of the uniting atoms may be, the combing power of the attracting element is always satisfied by the same number of these atoms." This view appeared to him (Prof. Williamson) to have been due to a habit of mind naturally prevailing in many studies, but which, he thought, we had found reason in our scientific work to abandon—he meant the absolute as opposed to the relative.

Prof. Williamson then went on to say that he knew of no limitation to atomic value; he did not say there were no limitations, but he did know that many elements have atomic values greater than those commonly assumed.

We found that the character of the atoms materially affected the result; thus gold could not combine with more than three atoms of chlorine alone, but it could take up an additional atom of chlorine if supplied with an atom of sodium at the same time. In this way we got the common double chloride of gold and sodium, $NaAuCl_4$, in which the gold is pentavalent.

We were not to consider the sodium as being here combined

with gold as such, it is combined with the whole group $AuCl_4$, a radicle that is doubtless far more chlorous than chlorine itself.

If any were inclined to doubt the truth of this view, they should write the formula $ClNH_4$ under $NaAuCl_4$, when they would perceive that the radicle $AuCl_4$ corresponded to NH_4, ammonium, the basylous properties of which no one doubted nowadays.

In ammonium we have the basylous energies of four hydrogen atoms concentrated by the inert nitrogen, and the result was a powerfully basylous radicle; in $AuCl_4$ we have the chlorous energies of four chlorine atoms giving a powerfully chlorous radicle.

Among other examples of the kind the Professor cited:

$$K_2AsF_7 \text{ with nonovalent atom.}$$

$$\left.\begin{array}{l} K_2PtCl_6 \\ K_2SiF_6 \end{array}\right\} \text{with octovalent atoms.}$$

$$\left.\begin{array}{l} OI(OH)_5 \\ KSbF_6 \end{array}\right\} \text{with heptavalent atoms.}$$

$$\left.\begin{array}{l} K_2FeF_4 \\ K_2MgBr_4 \\ K_2CuCl_4 \end{array}\right\} \text{with hexavalent atoms.}$$

$$KMgCl_3 \text{ with tetravalent atoms.}$$

And he concluded his address by drawing attention to the conditions that affect the atomic value of an element, which he said were, firstly, the nature of the combining atoms: there was a limit to the number of atoms of one kind that can combine with a given element, but if the element combined at the same time with one or more atoms of a different character, this limit might be passed; and secondly, the temperature, a sufficient rise of temperature being always accompanied by a diminution of atomic value. He thought it of great importance that these points should be considered by those who had artificially limited their horizon. The properties of many of the atoms in complex substances having been in great measure concealed from view by the practice of giving specific names, such as the word "molecular," he thought it would be much better to say at once that we are ignorant of the constitution of these bodies than to resort to such names.

JURASSIC BIRDS AND THEIR ALLIES [1]

ABOUT twenty years ago two fossil animals of great interest were found in the lithographic slates of Bavaria. One was the skeleton of *Archæopteryx*, now in the British Museum, and the other was the *Compsognathus* preserved in the Royal Museum at Munich. A single feather, to which the name *Archæopteryx* was first applied by Von Meyer, had previously been discovered at the same locality. More recently another skeleton has been brought to light in the same beds, and is now in the Museum of Berlin. These three specimens of *Archæopteryx* are the only remains of this genus known, while of *Compsognathus* the original skeleton is, up to the present time, the only representative.

When these two animals were first discovered they were both considered to be reptiles by Wagner, who described *Compsognathus*, and this view has been held by various authors down to the present time. The best authorities, however, now agree with Owen that *Archæopteryx* is a bird, and that *Compsognathus*, as Gegenbaur and Huxley have shown, is a Dinosaurian reptile.

Having been engaged for several years in the investigation of American Mesozoic birds, it became important for me to study the European forms, and I have recently examined with some care the three known specimens of *Archæopteryx*. I have also studied in the Continental museums various fossil reptiles, including *Compsognathus*, which promised to throw light on the early forms of birds.

During my investigation of *Archæopteryx* I observed several characters of importance not previously determined, and I have thought it might be appropriate to present them here. The more important of these characters are as follows:—

1. The presence of true teeth, in position, in the skull.
2. Vertebræ biconcave.
3. A well-ossified broad sternum.
4. Three digits only in the manus, all with claws.
5. Pelvic bones separate.
6. The distal end of fibula in front of tibia.
7. Metatarsals separate, or imperfectly united.

These characters, taken in connection with the free metacarpals and long tail, previously described, show clearly that we have in *Archæopteryx* a most remarkable form, which, if a bird, as I believe, is certainly the most reptilian of birds.

If now we examine these various characters in detail, their importance will be apparent.

The teeth actually in position in the skull appear to be in the the premaxillary, as they are below or in front of the nasal aperture. The form of the teeth, both crown and root, is very similar to the teeth of *Hesperornis*. The fact that some teeth are scattered about near the jaw would suggest that they were implanted in a groove. No teeth are known from the lower jaw, but they were probably present.

The presacral vertebræ are all, or nearly all, biconcave, resembling those of *Ichthyornis* in general form, but without the large lateral foramina. There appear to be twenty-one presacral vertebræ, and the same, or nearly the same, number of caudals. The sacral vertebræ are fewer in number than in any known bird, those united together not exceeding five, and probably less.

The scapular arch strongly resembles that of modern birds. The articulation of the scapula and caracoid, and the latter with the sternum is characteristic; and the furculum is distinctly avian. The sternum is a single broad plate, well ossified. It probably supported a keel, but this is not exposed in the known specimens.

In the wing itself the main interest centres in the manus and its free metacarpals. In form and position these three bones are just what may be seen in some young birds of to-day. This is an important point, as it has been claimed that the hand of *Archæopteryx* is not at all avian, but reptilian. The bones of the reptile are indeed there, but they have already received the stamp of the bird.

One of the most interesting points determined during my investigation of *Archæopteryx* was the separate condition of the pelvic bones. In all other known adult birds, recent and extinct, the three pelvic elements—ilium, ischium, and pubis, are firmly anchylosed. In young birds these bones are separate, and in all known Dinosaurian reptiles they are also distinct.

In birds the fibula is usually incomplete below, but it may be co-ossified with the side of the tibia. In the typical Dinosaurs, *Iguanodon*, for example, the fibula at its distal end stands in front of the tibia, and this is exactly its position in *Archæopteryx*, an interesting point not before seen in birds.

The metatarsal bones of *Archæopteryx* show, on the outer face at least, deep grooves between the three elements, which imply that the latter are distinct, or unite late together. The free metacarpal and separate pelvic bones would also suggest distinct metatarsals, although they naturally would be placed closely together, so as to appear connate.

Among other points of interest in *Archæopteryx* may be mentioned the brain-cast, which shows that the brain, although comparatively small, was like that of a bird, and not that of a Dinosaurian reptile. It resembles in form the brain-cast of *Laopteryx*, an American Jurassic bird, which I have recently described. The brain of both these birds appears to have been of a somewhat higher grade than that of *Hesperornis*, but this may have been due to the fact that the latter was an aquatic form, while the Jurassic species were land birds.

As the *Dinosauria* are now generally considered the nearest allies to birds, it was interesting to find in those investigated many points of resemblance to the latter class. *Compsognathus*, for example, shows in its extremities a striking similarity to *Archæopteryx*. The three clawed digits of the manus correspond closely with those of that genus; although the bones are of different proportions. The hind feet also have essentially the same structure in both. The vertebræ, however, and the pelvic bones of *Compsognathus* differ materially from those of *Archæopteryx*, and the two forms are in reality widely separated. While examining the *Compsognathus* skeleton, I detected in the abdominal cavity the remains of a small reptile which had not been previously observed. The size and position of this inclosed skeleton would imply that it was a fœtus; but it may possibly have been the young of the same species, or an allied form, that had been swallowed. No similar instance is known among the Dinosaurs.

A point of resemblance of some importance between birds and Dinosurs is the clavicle. All birds have those bones, but they have been considered wanting in Dinosaurs. Two speci-

[1] Read by Prof. O. C. Marsh before Section D, British Association, at York, September 2, 1881. Communicated by the Author.

mens of *Iguanodon* in the British Museum, however, show that these elements of the pectoral arch were present in that genus. Some other *Dinosauria* possess clavicles, but in several families of this sub-class, as I regard it, they appear to be wanting.

The nearest approach to birds now known would seem to be in the very small Dinosaurs from the American Jurassic. In some of these the separate bones of the skeleton cannot be distinguished with certainty from those of Jurassic birds, if the skull is wanting, and even in this part the resemblance is striking. Some of these diminutive Dinosaurs were perhaps arboreal in habit, and the difference between them and the birds that lived with them may have been at first mainly one of feathers, as I have shown in my Memoir on the *Odontornithes*, published during the past year.

It is an interesting fact that all the Jurassic birds known, both from Europe and America, are land birds, while all from the Cretaceous are aquatic forms. The four oldest known birds, moreover, differ more widely from each other than do any two recent birds. These facts show that we may hope for most important discoveries in the future, especially from the Triassic, which has as yet furnished no authentic trace of birds. For the primitive forms of this class we must evidently look to the Palæozoic.

SCIENTIFIC SERIALS

Journal of the Asiatic Society of Bengal, vol. l. part 2, No. 2 1881 (July 30), contains:—H. F. Blanford, F.R.S., on the relations of cloud and rainfall to temperature in India, and on the opposite variations of density in the higher and lower atmospheric strata, and description of a rain-gauge with evaporimeter for remote and secluded stations (plate 15).—J. Wood-Mason, on some insects belonging to the Rhopalocera from India and Burmah.—W. T. Blanford, F.R.S., on the Voles (Arvicola) of the Tibet Himalayas and Afghanistan (plates 1 and 2); and on *Myospalax fuscicapillus*, Blyth.

Gegenbaur's morphologisches Jahrbuch, vol. vii., part 2, 1881, contains—R. S. Bergh, on the organisation of the cilio-flagellate Infusoria; a phylogenetic study; plates 12–16. Contains diagnoses of the genera Ceratium, Dinophysis, Protoperidinium (nov. gen.), Peridinium, Protoceratium (nov. gen.), Diplosalis (nov. gen.), Glenodinium, Gymnodinium, Polykrikus, and Protocentrum, with descriptions of several species in each.—Dr. W. Pfitzner, on the minute structure of cell-nuclei.—Prof. Bischoff, on the third or lowermost frontal gyrus (Stirnwindung), and the inner upper lobulus-parietalis gyrus in the gorilla.

Zeitschrift für wissenschaftliche Zoologie, August, 1881 (vol. xxxvi. part 1), contains; Dr. H. Simroth, on locomotion and the organ of locomotion in *Cyclostoma elegans* and other indigenous land and freshwater mollusca (plate 1 and many woodcuts).—Dr. P. Stöhr, on the development of the skull in the Anura (plates 2 and 3).—Dr. A. Gruber, on division in the monothalamous rhizopods (plates 4 and 5).—F. Blockmann, on the development of *Neritina fluviatilis* (plates 6, 7, and 8).—Prof. W. Krause, on the human allantois (plate 9).

SOCIETIES AND ACADEMIES

Manchester

Literary and Philosophical Society, October 4, 1881.—J. P. Joule, F.R.S., &c., in the chair.—On drops floating on the surface of water, by Prof. Osborne Reynolds, F.R.S. It is well known that under certain circumstances drops of water may be seen floating on the surface for some seconds before they disappear. Sometimes during a shower of rain these drops are seen on the surface of a pond, they are also often seen at the bows of a boat when travelling sufficiently fast to throw up a spray. Attempts have been made to explain this phenomenon, but I am not aware of any experiments to determine the circumstances under which these drops are suspended. Having been deeply engaged in the experimental study of the phenomena of the surface-tension of water and the effect of the scum formed by oil or other substances, it occurred to me that the comparative rarity of these floating drops would be explained if it could be shown that they required a pure surface, a surface free from scum of any kind. For, owing to the high surface-tension of pure water, its surface is rarely free from scum. The surface of stagnant water is practically never free except when the scum is driven off by wind. But almost any disturbance in the water, such as the motion of a point of a stick round and round in the water, or water splashed on the surface, will serve to drive back the scum for a certain distance. This may be shown by scattering some flowers of sulphur on the surface. This powder is insoluble and produces no scum, and hence it serves admirably to show the motion of the surface and whatever scum there may be upon it. If when the surface is so dusted a splash be made by a stick so as to throw drops on to the sulphured surface, at the first splash no floating drops are produced; but after two or three splashes in rapid succession it will be seen that the sulphured scum has been driven back by the falling water, leaving a patch of clear surface, and on this drops will float in large numbers and of all sizes. These drops are entirely confined to that portion of the surface which is clear. The drops, either by their initial motion or by the current of air, glide rapidly over the surface from the point at which they are formed. When, however, they reach the edge of the scum they disappear, apparently somewhat gradually. I have this summer made the experiment on several ponds and on various days, and I have never found any difference. Any scum, however transparent, prevented the drops, and they always floated in large numbers when the scum was driven back in the manner described, by the wind or any other way. This result points to the conclusion that whatever may be the cause of this suspension, it depends only on the surface of the water being pure, and not at all on the temperature or condition of the air.—On the mean intensity of light that has passed through absorbing media, by James Bottomley, D.Sc., F.C.S.—Note on the colour relations of nickel, cobalt, and copper, by James Bottomley, D.Sc., F.C.S.

Vienna

Imperial Academy of Sciences, October 13.—V. Burg in the chair.—The following papers were read:—A. v. Liebenberg, experiments on the part of lime in germination.—E. Weiss, computation of the elements and ephemeris of Barnard's comet. —E. Brücke, on some consequences of the Young-Helmholtz theory.—T. W. Brühl, on the connection between the optic and thermic properties of liquid organic bodies.

Paris

Academy of Sciences, October 17.—M. Wurtz in the chair. —The Secretary presented the instructions formulated by the International Conference for Observation of the Transit of Venus. —Crystalline sulphurated copper (*cupréine*), formed at expense of old coins, apart from thermal springs, at Flines-les-Roches, Departement du Nord, by M. Daubrée.—Observations of the comet *b* 1881 (Tebbutt-Gould-Cruls) at Paris Observatory, by M. Bigourdan.—On a remarkable configuration of circles in space, by M. Stephanos.—On Fuchsian functions, by M. Poincaré. —On an experimental peculiarity relative to the equipotential law of Nobili's rings, by M. Guébhard. He has studied, under strong light, the trajectories of minute bubbles between electrodes in badly-conducting liquids; these are quite determinate and independent of gravity, and (friction and agitation of the liquid apart) seem to represent lines of force of the electric flow. With variously formed electrodes he has repeated Antolik's and Mach's experiments made with static discharge; and profiting by certain effects of polarisation, and counter-currents arising on quick reversal of the principal current, has obtained a fixed trace of the lines of flow.—Theory of a rapid vessel, by M. Pictet.—On the currents generated by atmospheric electricity and earth-currents, by M. Landerer. At Tortosa he stretched a wire between the roofs of two houses in a direction making a small angle with the magnetic meridian, and connected it with the water-pipes. The currents generated are variously due to condensation of aqueous vapour, to lightning-discharges, to action of wind, and to earth-currents. The first two and the fourth affect a telephone in the circuit, but not the third (these, however, as well as the second and fourth, deflect a galvanometer). The earth-currents are distinguished from atmospheric currents by their regularity and continuity during pretty long intervals. Variation of the earth-current is a sign of change of weather.—Action of sulphur on alkaline sulphides in very dilute solution, by M. Filhol. In such action on dilute solutions of monosulphide of sodium a polysulphide is formed, without notable production of hyposulphite, and it seems as though the original monosulphide has subsisted, spite of the dilution. But more probably it is decomposed and reconstituted.—On a new series of bases derived from morphine, by M. Grimaux. —On a new alkaloid of quinquinas, by M. Arnaud. The formula adopted for *cinchonamine* (this new alkaloid) is

$C_{19}H_{24}N_2O$. The author found it, simultaneously with cinchonine, in a very dense dark brown-red bark, of resinous fracture, from Santander; there being 0·8 to 1 per cent. of cinchonine, and 0·2 of the other. It differs from cinchonine in having two atoms more of hydrogen.—On the dissociation of carbamate of ammonium, by MM. Engel and Moitessier.—On the subcutaneous sacs and the lymphatic sinuses of the cephalic region in *Rana temporaria*, L., by M. Jourdain. He modifies the enumeration of sacs by Dugés, and indicates some relations hitherto overlooked. *Inter alia*, the lingual sinuses, forming cavities which communicate with the neighbouring reservoirs only by narrow orifices, form a nearly closed system, and M. Jourdain finds in this an explanation (different from that of Dugés) of the mechanism by which the tongue, become turgid, is protruded.—On a curious case of prefecundation observed in a Spionide, by M. Giard.—Contribution to a study of the Flagellata, by M. Kamsler. He has observed in *Cryptomonas ovata*, Ehrbg., transverse striation of the two flagellums serving for locomotion; also a group of long fine flagellums (hitherto unknown), which are also striated and serve for prehension of food; four layers in the body-wall, the outer one colourless, the others having chlorophyll (their structure is described): a spacious stomach with a sort of vestibule (but no œsophagean tube), intestine, and anus; small organisms therein, proving that Cryptomonas does not live on liquid food alone; a pore through which the contractile vesicle communicates with the exterior; an organ which is pro a ly a male apparatus, &c. He also describes the oculiform point in *Phacus pleuronectes*, Dugard, which organ he developed by cultivation in intense light. He considers the structure to prove its visual function beyond a doubt.—On the cause of immunity of adults of the bovine species towards symptomatic or bacterian charbon in localities where this malady is prevalent, by MM. Arloing, Cornevin, and Thomas. Most of the young animals in an infected district are spontaneously inoculated with various quantities of the virus, and while those receiving much take the disease in fatal form, those receiving little have a mild attack, sufficient to insure future immunity. M. Bouley remarked on the bearing of hereditary influences, and M. Pasteur on the error of supposing that young animals had a greater aptitude to receive contagion.

October 24.—M. Wurtz in the chair.—The following papers were read:—Detonation of acetylene, cyanogen, and endothermal combinations in general, by M. Berthelot. Gases formed with absorption of heat (acetylene, &c.), which do not detonate under simple heating, may be brought to explosion through sudden shock (*e.g.* through fulminate of mercury); this shock acts only on a certain layer of gaseous molecules, communicating enormous kinetic energy; the molecular edifice loses its relative stability and falls to pieces, and the initial energy is instantly increased by that corresponding to heat of decomposition of the gas. Hence a new shock produced on the next layer, which causes the same decomposition, and so on, to total destruction of the system.—On a general determination of the tension and volume of saturated vapours, by M. Clausius.—On an apparatus for determining, without pain to the patient, the position of a projectile of lead or other metal in the human body, by Prof. Bell. This is a modification of Hughes' induction-balance. One flat coil is superposed on another, so that the edge of the former is near the axis of the latter. One has thick wire, and is the primary circuit, the other has thin wire, and is the secondary. The two are dipped in paraffin and fixed in a wooden frame with handle. A vibratory current from a battery traverses the primary coil, and a telephone is put in circuit with the other. When the common part of the two coils comes near a metallic body silence gives place in the telephone to a sound which varies in intensity according to the nature and form of the body. It is found advantageous to insert in the two circuits two other coils similar to the first, but much smaller, and the common surface of which can be altered with a micrometric screw; also to insert an electrostatic capacity in the primary.—On the parasitic nature of disorders arising from impaludism, by M. Leverson. The efficiency of sulphate of quinine as an antidote is thus accounted for (various parasitic elements in the blood are described).—Note on the quality of waters of the Isère as regards the project of an irrigation-canal from the Rhone. Owing to the presence of salts of soda and magnesia in considerable quantity, the water of the Isère is absolutely unfit for irrigation.—On a configuration of fifteen circles, and on the linear congruences of circles in space, by M. Stephanos.—On the mathematical theory of the vibratory movement of bells, by M. Mathieu.—On the electrolysis of water, by M. Tommasi. A zinc-copper or zinc-carbon element, immersed in dilute sulphuric acid, does not decompose water, conformably to theory, if the two electrodes are of platinum. For this decomposition to take place, the positive electrode must be formed of a metal which, under influence of the voltaic current, can combine with the oxygen of the water.—On a proportion-compass (*boussole de proportion*) for measurement of resistances, by M. Carpentier. Suppose on the surface of a sphere, the vertical diameter of which is taken as polar axis, two similar circuits along two meridians at right angles to each other. Currents along these circuits affect a small magnetic needle hung at the centre of the sphere, which needle sets in the direction of the resultant of the two forces. This depends on the ratio of the intensities, and this ratio of the strength of one component to that of the other is precisely measured by the trigonometric tangent of the angle formed by the resultant with the other component. For measurement of resistances a current is made to divide between the circuits, and of course does so equally. Then the resistance to be measured is added to one circuit, and the current then divides inversely as the resistances. Two ways are indicated of eliminating the influence of terrestrial magnetism.—On the variation of the annual number of thunderstorms at Rio de Janeiro, by M. Cruls. In the period 1851–1876 (during which the annual number of thunderstorms is found to vary between eleven and forty-nine), he makes out a close correspondence between the curve of storms and that of solar spots. A curve for Toronto shows the same thing, though less distinctly. M. Faye expressed a feeling of reserve as to this correspondence. The period of spots could be reproduced in that of thunderstorms only if the spots sensibly affected the heat sent us by the sun; but no trace of an eleven-years' period has been found in annual temperatures. The conclusion is that solar spots and our thunderstorms are not in the relation of cause and effect. The correspondence indicated by M. Cruls is not sufficient to prove the necessity of finding a connection between the two phenomena.—On a new hydrate of carbon, by M. Morelle. He calls it *bergenite* instead of *bergenin*, the name given (1850) by its discoverer, M. Garreau, who did not study it very fully. It is got from Siberian saxifrage. M. Morelle arrives at the formula $C_{16}(C_4H_4O_4)_5$ (which corresponds to 75·75 per cent. of acetic acid). It is a pentatomic alcohol, ranking with pinite and quercite.—On the comparative toxicity of different metals, by M. Richet. Instead of injecting, he rendered the medium poisonous (*e.g.* the water for a fish). He named the *limit of toxicity* the quantity of poison per litre of water, allowing a fish to live more than forty-eight hours. Thus he shows that there is no precise relation between the atomic weight, or the chemical function of a body, and its toxical power.—Researches on the circulatory system of *Spatangus purpureus* by M. Kiehler.

BALFOUR'S "COMPARATIVE EMBRYOLOGY"

A Treatise on Comparative Embryology. By Francis M. Balfour, LL.D., F.R.S., Fellow and Lecturer of Trinity College, Cambridge. Vol. II. (London: Macmillan and Co., 1881.)

MR. BALFOUR has brought out the second volume of his treatise with admirable punctuality, and zoologists will find it no less valuable than the first. Indeed it is in many ways more attractive than the earlier volume, on account of the fact that the developmental history of the Vertebrata is here dealt with, and has an interest for a large class of anatomists who are not addicted to the study of other organisms. Moreover, in treating of the Vertebrata (or Chordata, as he prefers to call them when the group is so extended as to comprise the Ascidians) Mr. Balfour has introduced a very considerable amount of original matter.

The structure of the Vertebrata is not only more complex than that of other animals, but it is also better known, and has been more minutely discussed by anatomists; and similarly the development of various Vertebrate types has been more keenly scrutinised than that of other forms. Amphioxus, the lamprey, the salmon, the dog-fish, the frog, toad, and newt, the turtle and lizard, the common fowl, the guinea-pig, rabbit, bat, and even man, have formed the subjects of numerous memoirs devoted to one or other of their phases of development. This has been going on for many years, in fact ever since Remak and Kölliker laid the foundations of what may be called "cellular embryology." The chick, the frog, and the rabbit have during this period enjoyed the services of a class of workers difffering from those who have studied other animals. The latter have been naturalists interested in the study of embryology as throwing light on the affinities and origins of animal forms; the former have been distinctively medical men, who have sought in the minute study of the origin of the tissues of man and other Vertebrate animals indications which may be of service towards attaining the great desideratum of modern medicine, viz. a thorough knowledge of the physiology (*i.e.* the working of the mechanism) of man. Accordingly, from an early period the methods of the histological laboratory have been applied to the study of the Vertebrate embryo, and that by a large number of accomplished investigators, whilst it is only quite recently that the naturalists, as distinct from the medical men, have learnt to apply the same methods to the study of all organisms. There is at the present moment a movement from both sides and a fusion of the hitherto separate streams of "zoological" and "medical" embryology, which is marked as an epoch in the history of science by Mr. Balfour's treatise.

The medical histologist and physiologist has learnt that if he would comprehend the process of the cleavage of the egg and formation of the blastoderm and primitive organs he must not confine himself, as hitherto, to the limited area of comparison offered by the chick, the frog, and the rabbit; he must make common cause with the zoologist, and embrace the whole animal series in his view. He will, I cannot doubt, also soon openly acknowledge that the application of elaborate instruments of measurement to the nerves and muscles of dogs, rabbits, and frogs has furnished what knowledge it can in reference to man, and that if physiology is to move out of a barren path the whole evolutional series connected with man—the lowest as well as the highest—must be made the subject of experiment.

On the other side we find the field-naturalist—the lover of the forms and colours of animals—no longer content with a superficial study. To solve the problem which Mr. Darwin has succeeded in placing before him as the aim of his science, it is necessary that the minute structure of all animals—their cellular anatomy and embryology—shall be as accurately known as is that of the rabbit and frog to physiologists. Accordingly it is becoming more and more usual to find naturalists trained in the histological methods originated by the medical physiologists, and pursuing precisely the same inquiries as they do.

Since the germ-layer theory was shown to apply not exclusively to the Vertebrata, but, in a modified form, to the whole animal kingdom, embryology has become one body of doctrine equally significant for the practical ends of the medical man and for the speculative conclusions of the philosopher and naturalist. This fact is abundantly evident from Mr. Balfour's two volumes; in the earlier as in the present the chief aim is to trace the history of the units of structure known as cells from the parent egg-cell until the adult form is attained. The doctrine of cell-structure and that of evolution taken together serve to unite the interests of scattered and sometimes reciprocally contemptuous groups of scientific men—the physiologist and the naturalist will turn each with equal pleasure and profit to Mr. Balfour's treatise.

The embryology of the Chordata is first of all treated of, in the present volume, in zoological order. The terms Cephalochorda (for Amphioxus), Urochorda (for the Tunicata), and Craniata, which were proposed as divisions of Vertebrata in my "Notes on Embryology and Classification," are used, with some modification, by Mr. Balfour. Instead of Craniata the term Vertebrata is used, whilst in place of Vertebrata as formerly applied, the term Chordata is used. This change is open to objection, chiefly on the ground that it is more convenient to retain so well-known a term as Vertebrata for the more important group, and not to sink it in subordination to an unfamiliar term: also, as it seems to me, on the ground that the implication in both words "Chordata" and "Vertebrata," as used by Mr. Balfour, is delusive. All animals with a "chorda" would not necessarily take their place in the group of pharyngo-branchiate Chordata possessed of a tubular nervous axis and myelonic eyes, to which rather than Chordata the old name "Vertebrata" is appropriate—the Tunicates having been assimilated by the old-established group in the course of a natural process of the growth of knowledge.

The defence of the limitation of the term Vertebrata to the Craniate Vertebrates on the ground that they alone possess "vertebræ," raises the whole question of what we are to understand in the widest sense by the words "vertebræ" and "vertebrate." It seems to me to be difficult to construct a definition of either of these words

which will apply to structures present in the Lampreys, Sturgeons, Chimæra, and Dipnoi, and will not apply to structures present in Amphioxus. Gegenbaur's conception of the inapplicability of the term Vertebrata to forms devoid of myotomes as are the Tunicata, is, it seems, more reasonable. But even this objection is removed by the fact that in the tail of some Ascidian larvæ, and in Appendicularia, there are indications of segmentation of the muscular tissue.

However that may be, Mr. Balfour's account of the developmental phenomena exhibited by the various groups is of the greatest value, because it possesses three characteristics which also marked his first volume: it is complete as an epitome of all the very numerous and important contributions to the subject due to the Continental and English embryologists who have written so abundantly of late years; it contains a large amount of the author's original unpublished observations; and, lastly, it is no mere catalogue of the opinions of this and that authority, but is a critical treatise in which without arrogance, but with argumentative skill, a definite view as to the significance of the phenomena described, even when these are obscure and difficult of interpretation, is put before the reader. This latter feature gives Mr. Balfour's writings a special value, as pointing out lines of research for future observers.

The chapter on the Elasmobranchii is chiefly based on the author's original researches, which were published as a monograph. He has been extending his observations to the Cyclostoma and Ganoidei during the period in which he was also engaged in the preparation of the two volumes of the present treatise. Valuable original drawings (Figs. 38, 39, 40, 43, 45, 46 and 48) of sections of embryos of *Petromyzon Planeri* are given, and a correspondingly original account of the developmental history. Similarly the Ganoids, Accipenser, and Lepidosteus are illustrated by original drawings prepared from embryos supplied to Mr. Balfour by Prof. Salensky and Prof. Agassiz. In discussing the Amphibia much use has been made of the excellent figures given by Prof. Götte in his great work on the development of *Bombinator igneus*, but here again Mr. Balfour is able to rely upon original observations upon the newt, carried out in his own laboratory by Messrs. Scott and Osborn.

The fact that Mr. Balfour does not give us in a precise form a history of the development of the common frog from stage to stage, is explained by the special nature of his treatise, which aims at putting forward the generalisations of embryology and dealing with the developmental phenomena of the whole range of animal forms rather than providing the commencing student with a few selected examples of growth from the egg. Much is said about the common frog in the chapter on Amphibia, and from the general statements which it contains, in addition to the statements definitely relating to the frog, a nearly complete answer can be obtained to all questions which suggest themselves in relation to the main features of development in that animal.

The Birds are treated next in order after the chapter on Amphibia, and necessarily the common fowl—on which Mr. Balfour published some years since, in conjunction with Dr. Foster, a separate work designed for the use of junior students—is the source from the study of which his facts are derived. In this chapter, and in that on the Mammals, Mr. Balfour discusses the views of Kölliker as to the origin of the mesoblast from the epiblast of the primitive streak, and other interesting points raised, since his earlier work, by the observations of Braun on parrots and ducks, and of Gasser on geese.

The chapter on Reptilia is remarkably short, owing to the fact that very few observations have been made on members of this class, and that in many important points they agree with birds. Original drawings relating to *Lacerta muralis* and *Chelone midas* illustrate this section.

In dealing with the Mammalia Mr. Balfour has to depend chiefly upon the recent researches of Ed. van Beneden and of Kölliker, and his critical power and fair dealing is shown in the way in which he treats the points of disagreement between those two admirable investigators. The main outlines of our knowledge of the later development of the Mammalian embryo and its fœtal appendages were laid down many years ago by Bischoff and by Kölliker; but Mr. Balfour has given a particularly interesting account of the various modifications of the structure of the placenta presented by different mammals, illustrating his statement with woodcuts from the works of Prof. Huxley and Prof. Turner. With regard to the evolution of the placenta and the phyletic connection of the several forms seen in different recent Mammalia, he has some important original suggestions to offer.

It is impossible to give any idea, in a review such as this, of the abundance of facts and the thoroughness of treatment to be met with in the portion of Mr. Balfour's book which we have just noticed. It deals with the groups of Vertebrata one by one, and with the hundreds of questions which the greater or less knowledge of the particular group so far in the possession of embryologists, brings into existence in endless variety. The general results of such a method of exposition cannot be summarised in a review.

But such summarising has been to a very considerable extent carried out by Mr. Balfour himself in the latter two-thirds of the present volume, which will be found the most readable, and in some respects the most important, part of the whole work. We have a chapter on the comparison of the formation of the germinal layers and of the early stages in the development of Vertebrates, one on the ancestral form of the Chordata, and one treating of the mode of origin and homologies of the germinal layers in animals generally and of larval forms, their nature, origin, and affinities. To these chapters succeed twelve entitled "Organogeny," which actually constitute a treatise on comparative anatomy, based upon embryological data, under the headings (1) epidermis and derivatives; (2) nervous system; (3) organs of vision; (4) auditory organs, olfactory organs, and sense organs of the lateral line; (5) the notochord, the vertebral column, the ribs, and the sternum; (6) the skull; (7) pectoral and pelvic girdles and the skeleton of the limbs; (8) the body cavity, the vascular system, and the vascular glands; (9) the muscular system; (10) excretory organs; (11) generative organs and genital ducts; (12) the alimentary canal and its appendages in the Chordata.

In these chapters many of the facts which have been previously detailed in that part of the work devoted to the treatment of group after group are again brought forward

and looked at from a new point of view in relation to the doctrine of evolution, and facts which did not find their way into the earlier portion of the work receive consideration. Especially in the chapters on organogeny we find the questions connected with the probable first origin and later modifications of the nervous system and of the organs of special sense dealt with so as to supplement the earlier zoological chapters. It is not possible to single out for special notice any one of the discussions which may thus be said to sum up and give the general results of Mr. Balfour's work. But among the more interesting, as dealing with burning questions, are those relating to the origin of the limbs of fishes (based upon the author's recent investigations), and the nature of the excretory organs found in the different groups of the animal kingdom. In reference to the latter point Mr. Balfour commences his discussion with a remark which may be taken as an example of the judicial style in which he handles such problems. He says, "although there is not a little to be said for holding all these organs to be derived from some common prototype, the attempt to establish definite homologies between them is beset with very great difficulties."

The present volume is illustrated by about four hundred woodcuts, and consists of more than six hundred pages of royal octavo size. The first volume was of very nearly the same size, and as copiously illustrated. Together they form a contribution to that science of Biology which our countryman, Charles Darwin, has refounded and reformed, of which English men of science may feel justly proud. No work of the kind exists in any foreign tongue, and probably no such work would have been undertaken had not Mr. Balfour given himself to the task. Translations of Mr. Balfour's book are at this moment in course of publication both in Germany and in France. The thoroughness with which he has carried out the revision and incorporation of a few more than a thousand scattered memoirs by contemporary writers, and the excellence of his critical remarks and original observations and drawings, are all the more remarkable when it is remembered that only three years have passed since the work was commenced, and that during that time Mr. Balfour has been actively engaged in lecturing and teaching in his laboratory at Cambridge, has published several original memoirs himself, and has superintended the production of as many more by his pupils.

The University of Glasgow has recently recognised the importance of Mr. Balfour's labours in embryology by conferring upon him the degree of LL.D. *honoris causâ.*

Cambridge men, and all who hope for the restoration of the English Universities to their legitimate place in the academic sisterhood of Europe, must feel proud of Mr. Balfour and the steadily working school of biologists which has risen around the Trinity Prælector on the banks of the Cam. The Cambridge biologists are now a power in the scientific progress of the country, and it is from Cambridge that the new men come to fill positions as teachers of biological science in the colleges of Manchester, Birmingham, Dublin, Eton, and elsewhere. Few persons, however, know the smallness of the share which the University of Cambridge, as such, has had in this admirable development, and how necessary it is, if the present condition of activity is to continue within its boundaries, that adequate arrangements shall be made in permanence for the maintenance of the laboratories and for the salaries of those who are at present gaining honour for the University without receiving from it any return.

E. Ray Lankester

PRIMITIVE INDUSTRY

Primitive Industry, or, Illustrations of the Handiwork in Stone, Bone, and Clay of the Native Races of the Northern Atlantic Seaboard of America. By Charles C. Abbott, M.D. (Salem, Mass.: George A. Bates, 1881.)

THIS work is a valuable contribution to our knowledge of American archæology. Dr. Abbott describes successively the principal types of stone, bone, and bronze antiquities, especially those of New Jersey. The work is illustrated by more than 400 woodcuts, and is divided into 33 chapters devoted to "Stone Axes; Celts; Chisels and Gouges; Grooved Hammers; Semilunar Knives; Chipped Flint Knives; Drills; Awls or Perforators; Scrapers; Slick Stones and Sinew Dressers; Mortars and Pestles; Pottery; Sheatite Food-Vessels; Pitted Stones; Chipped Flint Implements; Bone Implements; Agricultural Implements; Plummets; Net-sinkers; Spear-points and Arrow-heads; Flint Daggers; Grooved Stone Club-heads; Pipes; Discoidal Stones; Inscribed Stones; Ceremonial Objects; Bird-shaped Stones; Gorgets; Totems; Pendants and Trinkets; Copper Implements; Hand-hammers and Rubbing-stones; Shell Heaps; Flint Chips; Palæolithic Implements; the Antiquity and Origin of the Trenton Gravels."

The number of stone implements which have rewarded Dr. Abbott's industrious search is really surprising. In New Jersey alone he has amassed no less than 20,000 specimens.

"From the great number of stone axes," he says "already gathered, and that remain to be gathered, from the area of the State of New Jersey, it is clear that this form of weapon or implement, as the case may be, was in constant and universal use among the Delaware Indians. In some localities, of several square miles in extent, there have been found from three to five axes in every one hundred acres, and still others are occasionally brought to light by the plough. Allowing but one-half the smaller number to have been left lying in every one hundred acres of the State's area, when abandoned by the Indians, there would remain, for the benefit of archæologists, the enormous number of one hundred and twenty-five thousand stone axes."

Considering the great abundance of stone implements, the rarity of typical scrapers in the United States is an interesting fact. No doubt many of the stone implements were used as scrapers, but I have hardly seen any specimens from Eastern America of the true typical North European and Eskimo form. Some of those figured by Dr. Abbott, though they may have served as scrapers, certainly are not of this type; and although others may be so, for instance that represented by Fig. 107, p. 124, it is difficult to speak positively, because Dr. Abbott does not give sections of the implements, so that in many cases their true form is doubtful. We would suggest to him to supply this omission in subsequent editions of his work.

Perhaps the most characteristic of American types are

the "spades" or "hoes," "oval plates of flint flat on one side and slightly convex on the other, the outline being chipped to a sharp edge." These differ principally from the European implements, which most nearly approach them, in their greater thinness. It is possible that they may have been used for agricultural purposes, and some bear traces of use, such as digging in sandy soil would produce.

Fragments of pottery are very abundant in New Jersey, but "unbroken articles of earthenware are rarely met with."

"A large portion of the pottery made by the Indians, however, was not made from pure clay just as it came from the bed, but the clay-earths that overlie the others were utilised and made available by mixing with them quartz granules and pounded shell. Much of the pure clay, which in many places was accessible, would need far more manipulation than the Indian potters would care to give it, and as the mixture of clay and shell was simpler and would meet all their requirements, it was, very naturally, most frequently used. They nevertheless possessed the knowledge of successfully working in pure clay, as sherds are found so made, and their well-formed clay smoking pipes are a further proof of the fact."

The forms are generally simple, and the ornamentation rude. The patterns are almost, if not quite, invariably geometrical; and generally made either with a pointed stick or bone, with the thumb-nail, with a twisted cord, or by covering the vessel, of course when soft, with coarse cloth.

Copper implements are comparatively rare, and Dr. Abbott is disposed to think that they—

"Were never designed for use as weapons or implements, but were intended for display upon special occasions, as for instance in their various dances, when much ceremony was observed, and various objects were displayed that at other times remained hidden in the custody of their fortunate owners, or of the appointed keepers, if tribal property."

He is clearly of opinion that they were merely hammered into form and never cast. They are always of very simple form.

As already mentioned, in one county of New Jersey alone Dr. Abbott has gathered no less than 20,000 stone implements. No one implement or pattern is peculiar to any one district, though certain forms abound in particular localities.

"Although in no instance has any one pattern of arrow-head been found so characteristic of a given locality as are the argillite fish-spears of the alluvial deposits along the river, it has frequently been observed by collectors that some particular form occurred in considerable numbers in a locality of very limited area, as a field or other small plot of ground. In my own collecting tours I have frequently noticed this, and can recall now certain fields that appeared to have only leaf-shaped arrow-heads, and others where the triangular pattern was alone met with. Even this is noticeable with other forms of chipped implements, and local collectors report fields, or other spots of a few acres, where only scrapers are found. This localising of certain forms has been so frequently noticed that it cannot be considered as a mere chance occurrence, yet it is scarcely susceptible of any rational explanation."

Dr. Abbott is of opinion that the Eskimo occupied New Jersey long before the advent of the Red Indian. To this earlier race he especially ascribes the implements made of argillite, which he regards as much older than the rest. Altogether he has found 4400 implements of this material, 233 being well-made drills or perforators and scrapers, the others spear-points, fishing-spears, arrow-heads, and knife-like implements. They are altogether ruder than the implements of flint and other materials, but

"Although it is true of these implements that they are of more primitive forms, and therefore probably older than the objects made of quartz and jasper, the argument does not rest so much upon this greater simplicity, as upon their decomposed condition, their occurrence at greater depths in the undisturbed soil, the greater adaptability of the spears for fishing purposes, and the absence of all indications in the deeper soils, of the utilisation of the minerals habitually used by the later Indians."

"For these reasons," he continues (p. 463), "it is claimed that we find sufficient evidence in them of a pre-Indian people—believed to be the Eskimo—who, it is further claimed, are the direct descendants of that still older race, the fabricators of the Palæolithic implements of the River Drift."

To many minds the most interesting question raised by Dr. Abbott's work will be the evidence as to the antiquity of man in America. Certainly some of the implements which he has discovered seem to belong to palæolithic types. In some cases he assures us they have been found in association with remains of the mastodon, and he is satisfied that those found in the Trenton gravels must be coeval with the gravels themselves.

The work concludes with a memoir by Prof. Henry Carvill Lewis on the Antiquity and Origin of the Trenton Gravel Beds. Prof. Cook is of opinion that they are of glacial origin, and derived from floods caused by the melting of a great continental ice-sheet. Prof. Lewis, on the contrary, maintains that they are post-glacial—in fact, a true river gravel of comparatively recent age. It cannot, he maintains, be assigned to the glacial epoch, except by assuming that there have been no river gravels deposited since that time, an assumption which he regards as quite untenable. On the whole, he concludes that there is no evidence which would render it necessary to assign to those gravels, or of course to the implements found in them, an antiquity of more than 10,000 years.

SACRED MYTHS OF POLYNESIA

Die heilige Sage der Polynesier—Kosmogonie und Theogonie. Von Adolf Bastian. (Leipzig: Brockhaus, 1881.)

PROF. BASTIAN, on a late journey made to enrich the Ethnological Museum of Berlin, stayed a short time in New Zealand and the Sandwich Islands, and there gathered some interesting information as to native traditions, some not yet published, and some which have been neglected (if ever met with) by European students. The documents now printed in a small volume all strengthen the opinion which has for years been gaining ground among anthropologists as to the civilisation of the Polynesians. It is true that they were found in Capt. Cook's time living in a barbaric state, and their scanty clothing and want of metals led superficial observers even to class them as savages. But their beliefs and customs

show plain traces of descent from ancestors who in some way shared the higher culture of Asiatic nations. At Wellington Prof. Bastian found Mr. John White, who, as a skilled translator of Maori, worked for Sir George Grey in bringing out the "Polynesian Mythology," and has been engaged in the study of native lore ever since. He is about to publish the results of his long study with the aid of the Colonial Government, and we have here as a specimen one of those mystic Maori cosmogonies which make us fancy we are hearing some Buddhist or Gnostic philosopher pour out his dreamy metaphysics about the origin of things. Out of the Primal Night, says the Maori poet, there divided itself Nothing, then came Darkness, then Seeking, and Following, and then such stages as Conception of Thought, Spirit Life, Desire, Coming into Form, Breath of Life, Space. All this is of a piece with the native Polynesian poetry in Taylor's "New Zealand," and that lately published by Judge Fornander in Hawaii. The poem that begins with the time when there was no voice nor sound, no day nor night, may remind us of the famous hymn of the Rig Veda that begins "Nor aught nor naught existed." We find here the well-known chant of Taaroa, how in the emptiness of space, when there was no earth nor sky nor sea, Taaroa passing into new forms became the foundation of the rocks and the sand of the sea, and the land of Hawaii was born as his shell. Prof. Bastian well compares this with the Scandinavian poem in the Edda, how there was no sand nor sea nor salt waves, no earth nor sky above, till Bör's sons made the mighty Midgard—earth. He points out, as he has already done, the curious likeness between the Scandinavian story of the fishing up of the monstrous Midgard-snake, and the South Sea Island tale of Maui fishing up the island of New Zealand. Not less striking is such an analogy as the Polynesian Taaroa mating with his own energy in female form, like a Hindu god with his Sakti. The author may well ask, are these people, with such far echoes of Orphic, Chaldean, Buddhist philosophy, the simple playful children of nature on whom we look down as representing the lowest rungs in the ladder of development? In Hawaii the German anthropologist learnt much from King Kalakaua, who is thoroughly initiated in the religious ideas of his royal predecessors, who used to have the eyes of their enemies offered them by the high priest in the stone bowl which his majesty still keeps as a curiosity. Out of the royal library he produced a MS. temple-chant, written about the beginning of this century, containing a cosmogony, of which Prof. Bastian reproduces as much as he had time to have translated. It has real poetry in it, and as a piece of child-like philosophy it is not without interest in its enumeration of the orders of beings, the grubs and worms, the sea-eggs and mussels, the seaweed in the ocean watched by the grass on land, the cranes and the gulls at sea watched by the hawks on land, and so on with trees and other creatures, till at last the gods come into being, and man rises out of the night. For a specimen of barbaric science may be mentioned the Maori myth told to the author by Mr. Davis, how the Moon arose out of the ocean, and still keeps the traces of this marine origin in its phases, which follow the ebb and flow of the tide.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Struggle of Parts in the Organism

ALTHOUGH I agree with the Duke of Argyll that the pages of NATURE are not adapted to a discussion on the general question of Theism, the letters which you this week publish leave me no alternative but that of entering upon the subject, so far at least as it seems desirable that I should now express my individual opinion on the points which your correspondents have raised.

My statement of what I conceive to be the position of the matter may best be rendered by answering first the questions which are put to me by Dr. Carpenter. He desires me to explain the "precise sense" which I attach to the phrase, "a general law whose operation is presumably competent to produce any set of phenomena," and proceeds in a most terse and lucid manner to expound the well-known and unquestionable truth that "in the *purely scientific* sense a 'law of nature' is nothing more than a general expression of a certain set of uniformities which the intellect of man discerns in the surrounding universe," &c. This is the only sense in which I have intended to use the term, and if my meaning has been obscured by speaking of a general law "producing" any set of phenomena, it is only because the idea of "a law of nature" as "any kind of *coercive* agency," or indeed anything other than "a generalised expression of facts," was so far from my mind that I perhaps too readily employed a convenient, though metaphorical,[1] mode of expression—just as one speaks of the sun rising, &c. In speaking then of Natural Selection as "competent to produce" certain phenomena I only meant that, given a certain set of activities and conditions supposed to be uniform, and the phenomena in question would occur, whether or not these activities and conditions are taken to be due to a disposing mind. So far, therefore, am I from maintaining "that there is anything in the *law* of Natural Selection that places it in a different category from every other," that my whole contention is exactly the reverse—namely, that the law of natural selection stands to certain observed phenomena of biology in just the same logical relation as, for instance, the law of gravitation stands to certain observed phenomena of astronomy. Indeed, it is just because I hold the laws of evolution to be so precisely identical in logical *status* with all other so-called laws of nature, that I see no better evidence of Design in "the adapted structures" of "the Human Hand" than I do in the adaptation, say, of a river to the bed which it has itself been the means of excavating.[2] In both cases I believe that physical causes have been at work (whether or not there have been metaphysical causes of a mental nature behind them), with the difference only that the one set are more complex and less obvious than the other. But in each case alike, if the physical causes are deemed adequate to furnish a scientific explanation of the effects, there is no residual effect to be carried over for explanation by any metaphysical theory of Design. Design, of course, there may be in both cases; I only maintain that if the laws of evolution are conceded to stand to the structure of an organism in the same logical relation as certain other natural laws stand to the structure of a river's bed, then, *ex hypothesi*, the one set of adaptations constitutes no *evidence* of Design different in kind from that furnished by the other.

This appears to be the point where my opinion has had the misfortune to be found at variance with that of the Duke of Argyll. For in his last letter he says that "there are in nature a few [? many, *vide infra*] cases of apparent adaptations and of

[1] *I.e.* "metaphorical" as investing a natural "law" with the signification of a natural "cause." A law of nature I take to mean a general proposition or formula which expresses the observed operation of certain physical causes, whether or not these are known. Therefore, although it is, strictly speaking, incorrect to say that "natural selection is a law competent to produce adaptations," in using such a form of expression one may be understood to mean "the sundry physical causes, whose joint operation is formulated by the law of natural selection, are competent to produce," &c.

[2] This illustration is borrowed from Mr. Wallace, who, in his "Natural Selection," elaborates it very instructively.

orderly arrangements of a very simple kind which do not necessarily suggest Mental Purpose. They may be the effect of what we call accident, or of the action of elementary laws under no guidance or direction. Inorganic phenomena furnish many examples of such arrangements," &c., the argument proceeding to the conclusion that "the writers of the last generation were perfectly right in resting the general Argument from Design on the separate instances of adaptation in which the mark of Mind is most signal and conspicuous"—*i.e.* in organic structures. Now until it is shown wherein we are justified in classifying natural laws under two such categories as "elementary laws under no guidance or direction," and laws whose "action" gives rise to "separate pieces of evidence pointing to the operations of special design"—until this is shown I must remain of the opinion that "Mr. Darwin's theory of Natural Selection" *does* "touch this argument" of scientific teleology. The distinction between two such sets of general laws is clearly not one that can be recognised by science, and if it is conceded that the theory of Natural Selection is competent to explain the proximate or physical causation of "structural adaptations," we have no more right to refer the latter to ultimate or metaphysical causes than we have so to refer "orderly arrangements of a very simple kind which do not necessarily suggest Mental Purpose." For if this concession is made it means that the one set of causes differs from the other only, as I have said, in being somewhat more complex in character and less obvious in operation.

Again, the Duke of Argyll says he is "not able to accept" the distinction which I drew between scientific and metaphysical teleology. The distinction nevertheless remains, and it seems to me so obvious that I must suppose the Duke has in some way failed to appreciate my meaning. However he says, "The fundamental proposition of all arguments from Design is simply this: that the exquisite adaptations to special ends which are conspicuous in organic nature are, and can only be, the work of physical forces when these are under the combination and direction and control of Mind." But this is not "the teaching of the great masters" whom Dr. Carpenter names in his letter.[1] To some of them, at any rate, such a needless restriction of the argument to special adaptations in "organic nature" seemed unwarrantable, and since Mr. Darwin has shown how these special adaptations may be proximately explained by the operation of certain physical causes, the tide of theistic opinion has more than ever turned towards a still more "fundamental proposition" of the argument from Design, viz. that the harmonious uniformity of Nature as a whole demands some one co-ordinating principle as its explanation. And when from this proposition it is argued that the principle in question must be of a psychical character, the argument belongs to the province of what I have called metaphysical teleology. This, indeed, is merely the "Cosmo-theology" of Baden-Powell, who saw very clearly the distinction which I have endeavoured to present, and while inveighing more heartily than I have done against "the narrow and unworthy form in which the reasoning has been too often conducted," maintained that the "fundamental proposition," "the very essence of the whole argument, is the invariable preservation of the principle of *order*," &c.

Lastly, I do not understand the Duke where he says that I am much mistaken if I "suppose that the present generation is satisfied with the purely materialistic explanations of adapted structures which are erroneously supposed to be the final result of Mr. Darwin's theory." I have not said anything to imply that I supposed these explanations to be "purely materialistic." As a matter of individual opinion I do not think that in themselves they are. I see plainly enough that they have reduced the "exquisite adaptations conspicuous in organic nature" to the same general category of physical causation as all other phenomena in the physical universe; but for this very reason, if for no other, I should fail to see that they can be "purely materialistic" in the sense of touching the transcendental or extra-scientific question of Theism.

Having thus stated my views at some length, I shall take no further part in this correspondence, unless it should appear that some further explanation is desirable.

George J. Romanes

[1] Except, perhaps, Mill, who thought highly of this form of teleology. But he also thought that if Mr. Darwin's "remarkable speculation" should be established as a truth of science, it would seriously "touch" the argument, as showing that "creative forethought is not absolutely the only link by which the origin of the wonderful mechanism of the eye may be connected with the fact of sight," &c.

Prof. Stokes's Lectures on Solar Physics

The subject of these lectures (Nature, vol. xxiv. pp. 593, 613) related primarily to the sun, and I was concerned with certain magnetic or electrical phenomena which are observed at the earth's surface only in so far as they related to the elucidation of the physics of the sun. Accordingly these collateral subjects were treated only very briefly, and I did not attempt to give anything like a history of the discoveries which have been made in them, even as regards the portions which bear more immediately on the physics of the sun. Indeed in many cases I designedly refrained from mentioning names, lest the hearers should suppose that I was giving a history of the subject, and those whose names might not appear in the very imperfect notice which it would have been should feel aggrieved. When a phenomenon was well known I generally contented myself with referring to it as such. Thus, for example, in alluding to earth-currents I spoke of them as what the progress of telegraphy had made us "familiarly acquainted with"; I said nothing about their discovery by Mr. Barlow, as described in his important paper published in the *Philosophical Transactions* for 1849, though it was a paper I had studied in connection with the lectures. I hope this example may suffice to prevent any one whose name does not appear from feeling annoyed at the omission, and to prevent the readers of Nature from taking my lectures for what they were not intended to be, namely, a complete history of the subject. I take this opportunity of referring to one passage in my second lecture (Nature, p. 415, a little above the figure), where I say "we might not have tension enough to produce such a discharge [*i.e.* a flash of lightning], the resistance to the passage of electricity from one portion of the air to another, which at any rate would be comparatively dry compared with what we have in warm latitudes, would prevent it by itself alone." These words, without actually asserting, seem to imply that the resistance to such a discharge through moist air would be less than through dry. My attention has been called by a friend to the fact that it has been found by experiment that moist air insulates as well as dry. I have not met with experiments tending to show whether the resistance to a *disruptive* discharge is the same or not in the two. Be that as it may, it does not affect what follows; for we know as a fact that thunderstorms are absent in high latitudes.

Cambridge, November 8 G. G. Stokes

The Society of Arts Patent Bill

It appears that "the draft of a Bill for the Amendment of the Patent Laws has been prepared by a committee of the Society of Arts, and is published by the Council of that Society for consideration."

From the printed bill so prepared and published the following extracts are made:—

Extract from the Proposed Patents for Inventions Bill.

Section 3. "An invention is deemed new for the purposes of this act if it has not been published or publicly used in the United Kingdom, the Channel Islands, or the Isle of Man within the thirty years immediately preceding the date of the application of a patent for it.

"5. A patent may be granted under this act for:—

"(*a*) Any manufacture or any product not being a natural product;

"(*b*) Any machine, or any means of producing any manufacture, product, or result;

"(*c*) Any process or method of producing any manufacture, product, or result;

"(*d*) Any part of a machine, means, process, or method of producing any manufacture, product, or result.

"8. *Commissioners of Patents and Examiners.*

"(1) There shall be a Board of Commissioners of Patents for Inventions, in this act referred to as the commissioners:—

"(2) At any time after the passing of this act Her Majesty may, by warrant under the Sign Manual, appoint three persons to be commissioners, of whom one shall be experienced in engineering, one shall be experienced in chemistry, and one shall be experienced in the law.

"9.—(1) The commissioners may from time to time after the passing of this act, subject to the approval of the Treasury, appoint such persons qualified by knowledge of manufactures or science or arts, as they see fit, to be Examiners of Patents.

"*Infringement of Patents.*

"57. An action or other proceeding for infringement of a patent shall not after the commencement of this act be commenced in any of Her Majesty's Courts of Justice in England.

"58. For the purposes of this act a person is deemed to infringe a patent if he copies altogether or in part the invention of a patentee with the view of effecting the same or a like object, and fails to establish any of the pleas allowed by this act in a proceeding for infringement.

"59.—(1) A patentee may complain of any infringement of his patent to the commissioners.

"(2) The complaint shall be heard and determined by the commissioner (other than the legal commissioner) who is best acquainted with the subject-matter of the complaint, assisted by a legal assessor to be appointed for the purpose by the commissioners.

"(3) An appeal shall lie from the decision of the tribunal thus constituted to the three commissioners, who shall hear the complaint *de novo*, and their decision shall be final.

"(4) The commissioner or commissioners sitting to hear any complaint may decide all questions of law and fact, &c.

"60. The pleas allowed by this act in a proceeding under this Act for infringement of a patent are—

"That the particular matters alleged to be infringed do not show sufficient invention to justify the grant of a patent, or are not new within the meaning of this act;

"That the patentee is not the true inventor of the invention, or of so much of it as is alleged to be infringed;

"That the matters complained of do not amount to infringement;

"That the claim of the patentee as respects the matters complained of is not stated with sufficient clearness;

"That the specification is, as respects the matters complained of, incomplete or misleading;

"That the patentee, as respects any matter complained of, withheld that which he knew to be a better description than that given in the specification."

. . . .

In commenting upon the above extracts it may be remarked that one main object of this bill appears to be to raise "*experts*" to the dignity and duties of the judicial bench. It is something quite new in the legal history of this country to make a man a judge because he has been frequently examined in court as a witness, and has shown considerable skill in baffling a hostile counsel.

The originality of such a proposal cannot be disputed, and accordingly the advocates of the present bill are justified in stating that it "provides for the trial of patent cases in an entirely new *manner*." What that manner is will be understood by referring to some clauses in the bill, the provisions of which are admirably non-legal in their phraseology.

By Section 57, "An action or other proceeding for infringement of a patent shall not, after the commencement of this act, be commenced" (in the only place where it can be brought, viz.) "in any of Her Majesty's courts of justice in England."

By Section 59, "A patentee may complain of any infringement of his patent to the commissioners."

Who then are to be the commissioners who are to stand in the place of the Lord Chancellor, the Master of the Rolls, and the law officers of the Crown, and who are to assume the functions of Judges of the High Court in ruthless disregard of the operation of the existing law?

By Section 8 they are to be three persons, "of whom one shall be *experienced* in engineering, one shall be *experienced* in chemistry, and one shall be *experienced* in the law." That is to say, they shall consist of two experts and a barrister.

To them the trial of all actions for the infringement of patents is to be relegated, but the proceeding is not to be called an action, it is to be "a complaint," and pleas only are to be raised by the defendant. It is here that the reformers, assisted by their barrister, show a wonderful capacity for disintegrating the law of patents.

They begin by defining the subject matter of a patent. This opens an opportunity for a display of strength, and they complacently remark that "at present the ancient definition of the Statute of Monopolies is in force, but, as a matter of fact, the question of subject matter depends wholly on the decision of the courts."

This is true, for we have from the period of James I., and especially since the invention of the steam-engine, a series of judgments which have enunciated with remarkable clearness and force the principles which should guide the courts in dealing with any future patent wherein it may be doubtful whether or not the thing patented is the proper subject for a patent right.

But instead of deciding any new case upon principle, our reformers give us a definition, or rather they give four definitions, the third of which is large enough to swallow all the rest, and would probably satisfy the most ardent inventor.

Hereafter the subject of a patent shall be

"*Any method of producing any result.*"

In spite of the protection afforded by the able Commissioners and their far-reaching staff of examiners, it may be doubted whether the public will feel quite safe in allowing monopolies to grow under the light of this definition. It may seem perhaps a little too general, it may include a few things more than the reformers have dreamed of.

Next, as to priority of invention:—

According to the Statute of Monopolies, patents may be granted for fourteen years for the "sole working or making of any manner of new manufacture within the realm to the *true and first inventor and inventors* of such manufactures which others at the time of making such letters patent shall not use," &c.

Hitherto a patentee must be the *first* inventor of the invention for which a patent is granted. Hereafter this distinction is abolished. "An invention is to be deemed *new* which has not been *published* or publicly used in the United Kingdom within thirty years immediately preceding the date of the application."

Lord Westbury has laid down "that the prior knowledge of an invention to avoid a patent must be such a knowledge as will enable the public to perceive the very discovery and to carry the invention into practice."

But inventions are now to be swept away by neglect and disuse. A process of de-publication is originated, whereby after thirty years neglect an invention may be deemed never to have been published, and the books wherein it has been described may be regarded as non-existent.

It has been a maxim of the law that when the public have once become possessed of an invention by lawful means, the right to use it can never be taken away from them. All this is done away with.

In what manner the promoters of this bill intend to work out their scheme of giving new birth to old inventions can hardly be understood from the above definition of a new invention, but the clause would appear to lead to endless confusion and uncertainty.

Next, as to infringement:—

By Section 58 "a person is deemed to infringe a patent if he copies altogether or in part the invention of a patentee with a view of effecting the same or a like object, and fails to establish any of the pleas allowed by this act in a proceeding for infringement."

The pleas are quoted in our extract from the bill, and a defendant may plead:—

"That the claim of the patentee as respects the matters complained of is not stated with sufficient clearness."

At present, as Lord Justice James has pointed out, there is nothing in the Statute of Monopolies or the patent law which says anything about claims. The legitimate object of a claim is the protection of the patentee, and a specification may be perfectly good without any claim at all. If there be a claim, the specification and claim are read together, and the claim must be construed with reference to the whole context of the specification.

According to the old practice a defendant would plead that the specification (whereof the claim, if there be one, forms a part) is insufficient.

According to the proposed bill the plea is to take the form:— That the *claim* is not stated with *sufficient* clearness. A plea to the sufficiency of clearness is somewhat embarrassing to a lawyer. Has it any meaning? and if so, what does it mean? The clearness which satisfied the patentee when he applied for his patent may not be sufficient to satisfy the commissioners when they are sitting in judgment. There may be some amount of clearness, but not enough. In the end, a patent may be wrecked on a mere verbal criticism, the very thing which the courts of law now set their faces against.

The infringement of a patent *only* takes place when a man *copies* the invention forming the subject-matter thereof. To limit an act of infringement in this way is absurd, and would

not be tolerated for an instant, as any patent lawyer would know.

As a matter of fact, there is a case pending which shows the risk of inventing new law. A company has brought an action for the infringement of a patent for making dynamite, the question being whether a man infringes a patent by acting as custom-house agent for admitting into this country a quantity of dynamite made abroad in infringement of an English patent. The Court of Appeal has given its judgment, and the case may go to the House of Lords. None of the six pleas enumerated in the draft bill will raise the question. And they will not raise another question which came up during the trial. The plaintiff company was formed to take over the dynamite patent from a prior company which then ceased to exist. The prior company assigned the patent to the plaintiffs with some very large words as to legal rights, and it became necessary to decide whether or not the second company could sue for infringements of the patent committed while the first company held it. The defence, that the right to sue for a tort is not assignable, could not have been raised under the proposed statutory pleas. Any plea which puts in issue the title of a complainant is inadmissible.

Lastly, as to the trial of a complaint of infringement :—

By Section 59 a complaint is to be heard in the first instance by the expert commissioner who is best acquainted with the subject matter. This judge is to be guided by a legal assessor, who will direct his mind into legal channels.

"From the decision of the tribunal thus constituted" (*sic*) an appeal will lie to the three commissioners, that is to say, to the original expert who has given his decision, to his brother expert, who is not experienced in the subject matter, and to the legal expert.

In other words, suppose the patent to be for a mechanical invention, and that we have three commissioners, A, B, C, of whom A is an engineer, B is a chemist, C is a lawyer.

A hears the case and gives his judgment ; B knows nothing of mechanics, and reviews A's judgment with the advantage of having A at his side to keep him in the right path according to A's views, while C acts as a sort of legal adviser, it being part of the scheme that there shall be no models, without which it can scarcely be hoped that B and C will ever get so far as to understand the invention.

This is the mode of trial which it is gravely proposed to substitute for the present inquiry in a court of law, with a right of appeal, first, to the Court of Appeal, and afterwards to the House of Lords.

Here ends one part of the new bill. The procedure in obtaining a patent can only be carried out if commissioners are appointed according to the provisions already discussed. This will I appear to be too improbable to justify any further encroachment upon your space.

LEX

"The Lepidoptera of Ceylon"

THE Colonial Government has recently presented to the library of this establishment Parts I. and II. of the work above named, for the publication of which it granted a large sum of public money. The origin of the book was the existence here at Peradeniya of a very fine series of original drawings made during a course of years by the well-known botanical draftsman in the employ of the Gardens—Mr. William de Alwis—under the careful supervision of my eminent predecessor Dr. Thwaites. The plates now published are copies of these figures (the originals are in the Colombo Museum), and to these, Mr. F. Moore has added brief technical descriptions. As a botanist it would be presumption in me to express an opinion as to the merit of the text of an entomological book. There are thirteen new genera in the first part and six in the second, but only three out of the nineteen contain any new species ; so at all events we get plenty of changes in the names of many long and well-known butterflies. But in the interests of scientific literature in general, I feel bound to enter a protest against the legend printed at the foot of every plate, "F. C. Moore, del. et lith.", as it is incorrect as to the facts. I have already stated by whom the figures were really drawn ; it is however only fair to the unassuming Sinhalese artist to allow that as put on the stone and published they are very greatly inferior to the admirable originals. One would like to think that it was a consciousness of this that led Mr. F. C. Moore to substitute his own name for that of W. de Alwis. But however this may be, it is time that some explanation was given by him of what looks like very shabby treatment of one of the best and most deserving natural history artists of the East.

HENRY TRIMEN

Royal Botanical Gardens, Peradeniya, Ceylon, October 10

An Alleged Diminution in the Size of Men's Heads

WHEN the hatter's note was brought before the Council of the Anthropological Institute, I supported its reception and publication ; my own observations have led me to the same conclusions. Setting aside for the moment the consideration of the authenticity of the statement—and I am not surprised that Prof. Flower should ask for more evidence—I would beg to call attention to the statistical results affecting infantine mortality, which are so well known to us in the statistical world. As we all know, it is a matter of congratulation that the rate of mortality in the periods from birth to two years, and from that to seven years, has much diminished in this country. This being so, the result is inevitable that many of the weaker infants that in a bygone day did not survive have now been saved ; and their survival means the survival of so many weaklings. It appears to me that this is going on in the United States and in many neighbouring parts of Europe. The question of degeneracy under sanitary influence is well worthy of attention and investigation. While on the one hand we see in the streets fewer cases of deformity and of squinting owing to orthopædic advances, there are many stunted individuals. The ears appear to me to be below the old standard in men and women. A well-formed ear was much more common in England than now. It also seems to me that the period of maturity in men (not puberty) is often later. The remark has been made that frigidity is more prevalent in women. It has come under my notice that the children of fine parents are often stunted, not belonging to the short races in the country, but being really stunted. We must always allow for a portion of the offspring belonging to the tall races, and a portion to the short races in the same family in England. My own belief is that the women are better than the men, and that when the effects of sanitary and medical improvement have become constant, that even the inferior women will exhibit a greater tendency to normal production. It is possible that the evil may be to some extent corrected by barrenness and frigidity. Looking back, I can find no effective cause in tight-lacing, as bad formerly as now, thicker or thinner hair since wigs, nor in wearing the hat.

32, St. George's Square, S.W. HYDE CLARKE

Sound-producing Ants

WITH reference to a remark of Mr. S. E. Peal's (NATURE, vol. xxiv. p. 484) to the effect that white ants emit sounds, but not in rhythm, I have to observe that I have frequently heard white ants emit sounds with the most perfect rhythm, when, in the years 1857–1860, I was engaged in the Geological Survey of Trichinopoly, &c. On several occasions it happened that my tent was pitched on a piece of ground infested with white ants, and it was the custom of my servants to spread a thin layer of straw beneath the *satrinji* or cotton carpet that was laid on the tent floor. Often, when sitting in the tent in the quiet of the evening, I have heard the white ants at work in the straw, emitting perfectly rhythmical waves of sound at intervals of about a second, or perhaps rather more. If they were disturbed by raising the *satrinji*, the sounds ceased : to be resumed however after a minute or two, when all was quiet again.

Simla, October 15 H. F. BLANFORD

Song of the Lizard

ANY one who has been in the South of Europe in the summer may have often heard a peculiar sound in the fields or amongst low herbage. The sound is like *wheet-t'wheet* repeated two or three times at short intervals. I have often been puzzled as to what animal it proceeded from, and should have supposed it to be some orthopterous insect, but that on getting to exactly where the sound had come from, it would again be heard at a distance of some five or six yards without having been seen. Last June, near Ajaccio, I believed I solved the puzzle. After the *wheet-t'wheet* a small lizard darted across some unusually bare ground, and, once again under cover, recommenced its song. Our great authority, Dr. Günther, is not aware of any true lizard having any vocal power (geckoes have a *tchet-tchet*—not often heard—are generally nocturnal, frequenting houses or old walls, occasionally hiding under stones during the day).

Perhaps the ability of some lizards to produce sounds such as I have here described may not be new to some of your readers.

1, Burlington Road, W., October 31 FRANCIS P. PASCOE

SEALS IN LAKE BAIKAL.—A. H. Keane wishes to know what authority there is for the statement made by E. Réclus ("Géographie Universelle," vi. 741) that seals outwardly resembling the *Phoca fœtida* of Spitzbergen are found in Lake Baikal; also what theories have been advanced to explain the presence of these Cetaceans in a freshwater lake over 1300 feet above sea-level.

NAPLES ZOOLOGICAL STATION.—For the terms on which permission can be obtained to work at the Naples Zoological Station, W. B. should write to Dr. Anton Dohrn, Stazione Zoologica, Naples.

MELAPTERURUS ELECTRICUS.—Keep it in an aquarium of fresh water, not too cold.

REV. J. F. T.—See the notice prefixed to our Correspondence Columns.

CHARLES W. HARDING.—You should communicate with the widow.

SEA FROTH

IN a letter written by my nephew, Mr. Ernest Gladstone of Aberdeen, describing the recent storms, he says: "When we got within a quarter of a mile of the sea we were astonished to see great flocks of foam, like snowballs, flying in all directions. A little further on we came to one of the large hollows in the links, and we saw a sight none of us had seen before; for the whole hollow, about 100 yards long and 50 broad, was one sea of slimy foam, of which a great part must have been about 10 feet deep. This was tossing up and down as if it were the sea itself. The waves of water broke far out at sea, but great rollers of foam kept rolling in towards the links, making it impossible to come near the sea without wading up to your waist in foam for nearly a quarter of a mile, and occasionally meeting a foam-wave up to your neck."

There is nothing unusual in this phenomenon, except the large scale upon which it took place. Almost every visitor to the seaside during rough weather must have observed the formation of a persistent sea froth, which is often carried great distances by the wind. The account, however, recalled to my memory some observations on the cause of the phenomenon which I made last year at Ilfracombe.

The white foam of a breaking wave, under ordinary circumstances, disappears almost as quickly as the small bubbles of entangled air can rise through the water and burst at the surface. It occurred to me that there must be something dissolved in the sea water which gave rise to the formation of the more persistent froth, and the broken and bruised sea-weed suggested itself to my mind as a probable source of such a substance. A quantity of it was therefore gathered, allowed to stand for several hours, till in fact it had run down to a liquid, and then filtered from the dirt and organic *débris* with which it was mixed. The clear water thus obtained gave a persistent froth, like that of beer, whenever it was shaken, and I subsequently found that it contained a considerable amount of organic matter. There was no distinct indication of anything albuminous.

In order to ascertain whether this property was due to broken sea-weed, two bottles were filled with ordinary sea water. Into one of these was put freshly-torn pieces of those kinds of fucus and other marine plants which were found growing between high and low water-mark, and in the other were placed strips of healthy laminaria freshly gathered from the lower zone. The bottles were violently shaken for a few minutes. The first gave a foam which quickly disappeared, while the second produced a froth which would remain more than twenty-four hours before all the bubbles broke. It may be observed in passing that this sea-froth, whether naturally or artificially prepared, becomes very iridescent on standing.

It seems fair to conclude, therefore, that the formation of this persistent froth is due to the destruction of the sea-weed—not of that which is tossed about by every tide, but of the laminaria which is uprooted and torn by the waves only when the violent agitation of the sea reaches a sufficient depth. J. H. GLADSTONE

OUR WINTER REFUGES—VENTNOR

IT is now upwards of half a century since Sir James Clark's classic work "On the Influence of Climate" in the prevention and cure of chronic diseases appeared, and among the more important results which followed its publication was the establishment of stations in this and other countries for meteorological observations, by which alone the climates of various sanatoria might be accurately compared. To Sir James is due to a great extent the merit of having placed the investigation of this important department of practical meteorology on a sound basis.

The late Dr. Martin of Ventnor was one of the most intelligent and active of the co-operating band of observers whose services were enlisted in the inquiry. A valuable series of observations was begun by him in the end of 1839, in establishing which Mr. Glaisher kindly gave his assistance and advice. The observations have since been carried on uninterruptedly, and they are evidently, particularly those of temperature and rainfall, of such a quality as quite to meet the objects aimed at. The results are presented and summarised in a just-published volume [1] by Dr. Whitehead with ability, in their bearings on the climatology of Ventnor.

The Isle of Wight occupies a high place as a favourable and commodious residence throughout the year for a large class of invalids, owing to the variety which it presents in point of elevation, soil, and aspect, and to the configuration of its hills and shores, which give distinctive climatic peculiarities to certain districts, notably to the Undercliff. These peculiarities are of no inconsiderable value in the treatment of those diseases which require a mild, equable temperature, a comparatively small rainfall, and protection from certain noxious winds.

The Undercliff extends for nearly seven miles from Bonchurch to Blackgang, with an average breadth of a third of a mile, and is completely sheltered from the north-east, north, north-west, and west winds of the Uppercliff—a range of lofty downs of chalk and sandstone which rise boldly behind the successive terraces in elevations varying from 400 to 600 feet. Since the Undercliff terminates in an unbroken perpendicular sea-cliff from 60 to 80 feet in height along its whole extent, the situation is not close or confined, but open and airy, and affords, besides, certain material advantages in the mitigation of sea fogs and low night temperatures. The broad belt of the Solent and Spithead separating the Isle of Wight from the mainland, and the position of the Undercliff in the extreme south of the island, considered with reference to the prevailing winds of the Channel, are also important factors in the climate of the district.

In more recent years several other meteorological stations have been established in other parts of the island and on the adjacent coast of Hampshire, from the observations of which a comparison may be made of the climatologies of this part of the South of England.

On an average of the last twenty-one years the annual rainfall of Ventnor was 30·00 inches, being all but identical with that of Osborne and Bournemouth. The amount rises successively at Hurst Castle, Ryde, and Newport, the rainfall at the last place being 34·20 inches,

[1] "The Climate of the Undercliff, Isle of Wight, as Deduced from Forty Years' Consecutive Meteorological Observations," by J. L. Whitehead, M.D.

or fully four inches in excess of Ventnor. While the rainfall of the comparatively low-lying coasts of the Isle of Wight and Hants is about 30·00 inches, the amount along the coast from Selsey Bill eastward as far as Folkestone is two inches less, but on the coast of Devon, from Lyme Regis to Start Point, it rises to from 33·0 to 37·6 inches—figures of some importance in their relations to the sanataria of these coasts.

One of the most interesting results disclosed by these forty years' observations is the successive gradual increase of the rainfall decade by decade, the means being respectively, beginning with the decade 1840-49, 25·72, 28·45, 29·16, and 31·11 inches. This feature of the rainfall holds also in several other districts of the United Kingdom; whereas on the other hand other districts present a very different distribution during these forty years, that of some districts being just the reverse of Ventnor. The mean rainfall of Ventnor for the twenty years ending 1859 being 27·08 inches, and for the twenty years ending 1879 being 30·14 inches, points to the necessity there is that care be taken to employ the same terms of years in comparing the rainfall of different districts.

The mean temperature for the forty years is 51°·6; the coldest month being January, 41°·9, and the warmest August, 62°·7. As January may be taken to represent the coldest months of the year, or the season when the climate of the Undercliff affords the greatest advantages to invalids, the following comparison of its temperature with that of other places in the South of England may be stated:—It exceeds the temperature of Sidmouth by 0°·2; Bournemouth by 0°·6; Osborne by 1°·2; and Folkestone, Eastbourne, Brighton, and Clifton by 1°·7; but on the other hand its January temperature is lower than that of Torquay by 1°·1; the extreme south-west of Cornwall by 2°·6; and Scilly by 4°·4. In this connection it is to be noted, as already pointed out, that along the coast to eastward the rainfall is less, and the climate therefore somewhat dryer; and to westward the rainfall is larger and the climate therefore wetter; and this latter remark applies with increased force as respects all places to the westward of Prawle Point.

The climatic advantages of the Undercliff, due to its southern insular position and distance eastward from the Land's End, by which the force of the west-south-west winds are much weakened before arriving there, are perhaps most apparent on examining the columns of minimum night temperatures. In this remark we refer to the general teaching of the figures, which indicate a remarkable protection against the inroads of low temperatures, with their malignant influence as respects a large class of invalids; and not to such singular temperature phenomena as the occurrence of 17°·0 on January 22 last, during the great snowstorm of that period, for if great or exclusive weight be given to such temperatures the winter climate of the Undercliff must yield to that of many insular situations in the north-west of Scotland.

As compared with London the mean temperature of the Undercliff is 2°·4 less in July, 0°·8 in August; but in September it is 0°·7, and in October 2°·2 higher. In other words the heat of summer is greatly mitigated on the south shores of the Isle of Wight, and prolonged further into the autumn months, thus greatly extending the time during which invalids might sit out in the open air with impunity.

Dr. Whitehead's book is handsomely bound, carefully got up and printed, and the tables are introduced to the reader by a well-written and sensible preface. When the work, however, passes into a second edition, one or two improvements might be introduced. A table of monthly mean temperatures of the several years might be given similar to that of the rainfall on pp. 29, 30. In this edition no mean temperatures of the months are included, and to ascertain these the whole of the temperatures must be copied out from pp. 8 to 23, and the averages struck. The table of monthly barometric means requires careful revision, several of them showing transposed and inverted figures, while a few others require to be compared with the original observations from which they are calculated—transpositions and inversions of figures not being so readily seen in barometric as in thermometric and rainfall averages. The work, however, is an exceedingly valuable addition towards a correct knowledge of the climatologies of the South of England, which holds out to invalids the best winter refuges of the British Islands.

INTERNATIONAL GEOLOGICAL CONGRESS

THE second session of the International Geological Congress was recently held at Bologna, commencing on Monday, September 26. About 200 geologists were present, but only eight of them represented the English-speaking nations. These were: Prof. James Hall (representing the United States), Dr. T. Sterry Hunt (Canada), W. T. Blanford (Geological Survey of India), W. Topley (Geological Survey of England), Prof. T. McK. Hughes, J. A. Phillips, E. B. Tawney, and Col. Tabuteau.

The arrangements made for the Congress were admirable in every respect, thanks to the energy and forethought of Prof. Capellini and M. Giordano.

The first session of the Congress was held at Paris in 1878. At that meeting certain geologists were nominated to organise committees in each country to discuss and report upon the various questions requiring attention. These are classed in three main divisions: (1) the unification of geological nomenclature (of this committee Prof. Hughes was nominated president for England); (2) the unification of colours, signs, &c., employed in geological maps and sections (of this Prof. Ramsay was nominated president for England); (3) nomenclature of species; on this subject no action has been taken in England. Prof. Hughes' committee has been for some time at work, and notices of its progress have at various times appeared in this journal. The Committee on Geological Maps was started in England much later, but a report of its work was read at the York meeting of the British Association. At that meeting the Association gave a grant of 25*l.* in aid of the proposed International Map of Europe.

Some preliminary meetings were held at Bologna on Sunday, September 25, but the real work of the week commenced next day, when the Congress was formally received by the Syndic and Municipality of Bologna. At the opening meeting the chair was occupied by M. Berti, Minister of Agriculture and Commerce, who had been deputed to represent the King. The chairman was supported by M. Q. Sella, honorary president, and M. Ed. Hebert, ex-president. The bureau was formed as follows:—President: Prof. Capellini; Vice-presidents, representing various nations, amongst them—J. Hall (United States), Sterry Hunt (Canada), W. T. Blanford (India), Prof. Hughes (Great Britain), Prof. Daubrée (France), Prof. Torell (Sweden), &c.; General Secretary: F. Giordano; Secretaries: Bornemann, Delaire, Fontannes, Pelar, Taramelli, Topley, Uzielli, and Zezi. The Congress had offered prizes for the best essays upon the colouring, &c., of maps. These were awarded to MM. Heim of Zürich, Carpinski of St. Petersburg, Maillard of Lausanne.

At the conclusion of this meeting the Congress adjourned to the excellent new Geological Museum which has been formed under the direction of Prof. Capellini. The Via Zamboni, in which the Museum is situated, was lined by representatives of all the ancient trade guilds of Bologna, each with its banner. M. Sella took especial pains to explain to the American and English visitors the history and present position of these interesting old societies.

The first sittings of the Congress were devoted to a

discussion of the names to be employed in describing the various groups of beds, on which subject a preliminary report had been prepared by M. Dewalque. English geologists have always used the term "formation" to denote a group of beds, sometimes large, sometimes small; thus we should speak of the Silurian formation or of the Liassic formation. The word is rarely used in this sense by Continental geologists; they use it only as descriptive of the mode of origin or *mode of formation*, or as descriptive of the nature of the material composing the rock. Thus they might speak of the "chalk formation," but never of the "cretaceous formation." It was necessary for the English to make some concession on this point, which should satisfy the representatives of other countries without unduly committing English geologists. Prof. Hughes proposed a resolution recommending the use of the word "formation" as far as possible in the Continental sense.

A long discussion followed respecting the value to be attached to certain words in descriptive geology, and ultimately it was resolved to employ them in the following order, the most comprehensive term being placed first:—

Divisions of sedimentary formations.	Corresponding chronological term.
Groupe	Cycle
Système	Période
Série	Époque
Étage	Age

With regard to the term *Série* a difficulty occurred, in consequence of there being no precisely similar equivalent in the German or Russian languages. This question was referred to the Council, who recommended the use of the terms *Série*, *Section*, or *Abtheilung* as equivalent terms. Also as regards the term *Assise* (subdivision of *Étage*) a reservation was carried leaving each nation to choose the word which most nearly expresses the same meaning (*beds*, *couches*).

There was much more down for discussion, especially with reference to proposed uniformity of language, terminations of words, &c; but it was resolved to postpone these questions till the next meeting of the Congress, by which time it might be possible to arrive at some common terminology for eruptive rocks, &c.

The second part of the work of the Congress related to the colours and signs employed in geological maps. On this subject a general report had been drawn up by Prof. Renevier, based upon the reports of various national committees. Much has been said about the solar spectrum and its order of colours, and Prof. Renevier's resolution, as originally drawn up, proposed a system of colour based on this natural order; but so many and important deviations from this natural order were recommended by different nations, that it was thought better to omit all reference to the solar spectrum. Resolutions were passed recommending the adoption of a common scale of colours for all nations, especially in view of general maps (*travaux d'ensemble*); but without reference to maps now in course of publication. The following colours were adopted:—

For crystalline schists of Pre-Cambrian age—bright rose-carmine.
,, ,, ,, unknown age—pale rose-carmine.
,, Palæozoic rocks (question reserved for Map Committee).
,, Trias—Violet.
,, Lias—Dark blue.
,, Jurassic—Blue.
,, Cretaceous—Green.
,, Tertiary group—Shades of yellow; the newer divisions to be the lighter tints.

The subdivisions to be shown by shades of the colour adopted, or by coloured lines; the darker shades denoting the older subdivisions. Sedimentary formations to be denoted by the initial Roman capital of the name of the formation; subdivision of formations to be shown, in addition to this, by the initial small letter of the name of the subdivision. Still smaller subdivisions to be shown by figures added to the other signs; the figures to be taken in chronological order—1 denoting the oldest subdivision. Eruptive rocks to be denoted by the initial Greek capital of the name of the rock.

The Congress resolved to prepare and publish a geological map of Europe, and for this purpose a committee was appointed. Any committee having representatives of all the countries of Europe would be too large; it was therefore necessary to limit the number of nations to be directly represented; at first this was fixed at five, but afterwards the committee was increased to eight. Great Britain received the largest number of votes, France coming second, Germany third. The committee was finally elected as follows:—Beyrich (for Germany, and also as director of the map); Daubrée (France); De Moeller (Russia); Giordano (Italy); Hauchecorne (as assistant director); Mojsisovics (Austro-Hungary); Renevier (Switzerland, and also as secretary); Topley (Great Britain). The map will be published at Berlin; the scale was fixed at 1 : 1,500,000; the cost is estimated at about 2500*l.*; and application will be made to the various Governments of Europe for monetary aid.

In most of the countries not directly represented, arrangements will subsequently be made by the committee; but it was settled that Austria should take charge of Turkey, France of Algeria, &c. (or of so much of that district as comes within the limit of the map), Great Britain of Palestine, it being hoped that much geological information, which may be available for this purpose, is in possession of the Palestine Exploration Society.

At a subsequent meeting it was arranged that a committee, formed for the most part of vice-presidents, should be formed to co-operate with the Map Committee with regard to questions of nomenclature, classification, &c. Prof. Hughes represents England on this committee.

One sitting of the Congress was devoted to a discussion of the nomenclature of species. Upon this question only the French committee had sent a report, and no great amount of work was done. The Congress, however, recommended the use of a generic and a specific name, to be followed, when necessary, by that of the variety. The nomenclature to be Latin or Latinised. When the original name of the genus is not preserved, the name of the author of a new specific name is to be placed within brackets.

At the close of the Congress an excursion was made to Florence, Pisa, and the marble quarries of Carrara. For this free tickets or a special train were provided for all members. At each place the municipality received the Congress and did its utmost to render the excursion a success. At Florence the new Museum of Natural History was inspected, and then the Congress adjourned to the crypt of San Lorenzo to place a wreath on the tomb of Steno (who died in 1687), and to hear an oration by Prof. Smidt of Copenhagen. At Pisa the Natural History Museum was visited, this being very rich in geological and prehistoric remains from the district.

An important result of the Congress has been the foundation of a Geological Society of Italy, of which Prof. Meneghini is president, Prof. G. Capellini vice-president, and M. Pantanelli secretary. So much good geological work is now being done in Italy that it is of great importance to collect the scattered workers into one central society.

The next meeting of the Congress has been fixed for 1884 at Berlin, with Dr. E. Beyrich as president; but preliminary meetings, with reference to the geological map of Europe, are to be held next year at Foix, in the Pyrenees (at the annual meeting of the Geological Society of France), and in 1883 in Switzerland. It was generally understood that the fourth meeting of the Congress would be held in England.

THE AUTUMN SKY[1]

II.

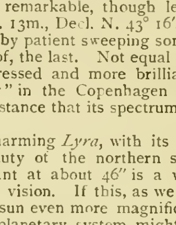
An attempt was made in a preceding paper to point out the most remarkable features of the planets that are at present so attractive for telescopic inquiry. We will now proceed to pass in review a few of the more interesting sidereal objects in that part of the heavens that is well placed for the observer. It is needless to say that within our limits nothing more can be expected than a very scanty selection, for the use of inexperienced students, of some of the most conspicuous of the many hundreds of double stars and nebulæ that are within the reach of ordinary instruments. We begin with the constellation *Hercules*, because it is rapidly gliding away from us, and the search for our first object should be undertaken as early as possible in the evening, especially if we are unacquainted with its position. The possessors, of course, of equatorial mountings and divided circles will readily find anything in our selection from its assigned place; but we propose to give such instructions as may be serviceable with altazimuth stands, aided by any common map, which will be occasionally supplemented by small diagrams. These, it must be borne in mind, correspond with a meridian position, and must be inclined one way or other to represent objects lying east or west of it.

If then we wish to find without an equatorial, set to R.A. 16h. 37m., D.N. 36° 41′, the great globular cluster in the constellation *Hercules*, known as M(essier) 13, we must look out west-north-west for a large triangle, nearly equilateral, of 3rd mag. stars β, δ, ζ, the left-hand angle of which at β is nearest the horizon; at the other end of this side is ζ; if we continue the line $\beta\zeta$ nearly as far again to the right, bending a little upwards, we come upon a similar star η, and between ζ and η, but rather nearer to the latter, our object is found. It is easily visible with the slightest telescopic aid, and discernible even without it in a clear dark sky. It will be instantly recognised as a round ball of misty light, which nearer the meridian would be of considerable brightness. It will not be favourably placed for examination; but those who have once caught sight of it will look out for it in a better position another year. At any time its resolution into stars will of course depend on the aperture; as this and the power are increased the mass will soon begin to sparkle, and the more brilliant points will rise out of the general haze; but it will require a large telescope to resolve it throughout. The great Copenhagen achromatic of 11 inches aperture in the hands of d'Arrest effected it with a power of 95. Its components, ranging according to Sir J. Herschel from 10 or 11 to 15 or 20 mags., must be thousands in number: his father had supposed 14,000. The state of compression, he observes, indicates not much greater density at the centre. Outliers surround it in streaky masses and lines; and the ball, according to the Earl of Rosse, is intersected by three dark rifts confluent towards the centre, which I have perceived, as *known objects*, with my 9⅓-inch mirror. This is unquestionably the finest specimen of a globular cluster visible in our latitudes; and even when the eye has recovered from its first surprise, it is never weary of reverting to this wonderful object. It may well be called wonderful, even at the distance at which we have to contemplate it. But imagination fails utterly to grasp the magnificence of such a scene, could we be transported to a standpoint two or three of its own diameters distant; or could we penetrate to the heart of the resplendent mystery, flaming on every side with suns innumerable, and where shade would be unknown and impossible. But are those thousands upon thousands suns indeed? We only know that they possess the solar character of intrinsic light; yet that there is something peculiar in that light appears by modern analysis, which finds the red end of their spectrum deficient; but as to their nature, or their magnitude, or their distance from us, or among themselves; whether they were formed as they are, or have been gradually aggregated through innumerable ages—of all this we know absolutely nothing, and nothing are we ever likely to know. Nor if, as it is natural to suppose, gravitation is an inseparable property of matter, can we conceive how that glorious accumulation can be permanent, or escape ultimate transmutation into a fresh form of existence by the final coalescence of its members. It has indeed been supposed that, under certain admissions as to proportionate distance and velocity, such a mass might be preserved in a permanent condition of rotation; but we are treading here too closely upon the impossible, and though all may continue sensibly unvaried for ages, yet a secret principle must be at work that will issue in a final catastrophe—the opening, it may be, of a new and more glorious existence. We beings of a day can but confess our ignorance and our nothingness in the contemplation of such an evidence of creative power and uncomprehended skill in what is but a minute speck to the keenest eye.

We should not leave this object without noting its beautiful configuration in a large field with neighbouring stars; probably only an optical vicinity. Yet who after all can say which may be the nearest, now that it has been so clearly shown that there is but a precarious relation between apparent magnitude and actual distance?

While we are in this region we should make an attempt to see another remarkable, though less-known, cluster, M 92, R.A. 17h. 13m., Decl. N. 43° 16′.[1] It may be found without circles, by patient sweeping some distance above, and to the left of, the last. Not equal in size to M 13, it is more compressed and more brilliant in the centre; "*formosissimus*" in the Copenhagen telescope. It is a singular circumstance that its spectrum resembles that of M 13.

Next, ever-charming *Lyra*, with its glowing sapphire, *Wega*, the beauty of the northern sky, whose minute 11 mag. attendant at about 46″ is a well-known test for sensitiveness of vision. If this, as we are warranted in supposing, is a sun even more magnificent than our own, a search for a planetary system might not be hopeless. Several observers have actually seen minute points in its immediate neighbourhood, but there is little agreement about them, and they remain for closer investigation. The accompanying diagram may serve to guide us to



1.

some other interesting objects here. Above *Wega*, a little to the left, are the two well-known pairs, ϵ^1, ϵ^2, with the intervening *debilissima*; long familiar to observers. It is no very uncommon feat, though one which I could never accomplish, to separate ϵ^1 and ϵ^2 at 3½′ distance with the naked eye; the subdivision of the pairs, and the ruddier hue of one of the components of ϵ^1, will be apparent with a power of 50 or 60. There is of course an abstract possibility that this beautiful combination may be merely the result of coincident direction: but our optical sense revolts from the demand this would make upon it; and

[1] Continued from p. 10.

[1] This glorious object, discovered by Bode, is omitted in Sir J. Herschel's Catalogue.

mere inspection forces home upon us the persuasion that a physically-connected system lies before the eye. As regards each pair separately, the inference is already established by orbital motion—the mutual relation of the whole waits the examination of ages.

The *debilissima* may be watched for a suspicion of variable light. Some very minute points precede them.

ζ, next below and following *Wega*, is a grand wide pair, nearly 44″ apart, 5 and 5½ or 6 mags., topaz yellow and greenish, or, according to others, lilac. Such discordant estimates of colour are of frequent occurrence. They

2.

may arise from actual dissimilarity of vision, or an uncertain effect of contrast, or residual chromatic aberration; but we have to remember that these star-hues are often open to question from their feebleness, and especially from the absence of comparison with a light of standard whiteness in the field.

To the left of ζ a low power will show us δ^1 and δ^2 in a fine group, where some beautiful colouring will be found. One of the smaller stars has at times appeared to me of a pale ruby tint, on other nights not traceable. 24′ nearly north of δ^1 Burnham has detected a small pair (his No. 137), only 1″·2 apart, and therefore a severe trial for ordinary apertures.

Further to the left the naked eye shows us two small stars at a greater distance: the uppermost, η, 5 mag., has a 9 mag. attendant at 28″; the colour is differently recorded as blue and pale yellow. Three small pairs lie near it. The other star, θ, is also worth looking at for its fine surroundings. But beautiful fields are throughout more or less the character of this constellation.

Lower down, and brighter than the two last-mentioned, are two considerable stars, β and γ, of which the right hand one, β, is the centre of a minute group; but more remarkable for variation in its light, with superposed inferior variations, completed in about 12d. 22h. Its

3.

colour is also questionable, yellow, or none. But greater interest attaches to these two stars as guides on either side to the wonderful annular nebula, M 57, the brightest of its class, easy with very slight optical means, refractory with the highest. Its light has been noticed, ever since Schröter's time, to be a little unequal in different parts, and may possibly be variable; the interior is gauzy and streaky, according to the Earl of Rosse, who also represents some exterior wispiness. The idea of its starry composition, maintained by Secchi and Chacornac, has been dispelled by Huggins, whose spectroscope shows only gas. But how produced? how accumulated into that extraordinary shape? how heated into incandescence, and maintaining that temperature, at any rate since 1779, amid the alleged intensity of cold in space—here even conjecture must admit its helplessness. A minute star following it may perhaps be variable.

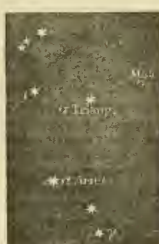
In sweeping from this region towards the galaxy, we shall cross an abundance of rich and lovely fields; but

4.

the galaxy itself, with a sufficient aperture and low power, is from end to end a scene of wonder and astonishment. Especially in some parts of *Cygnus* its magnificence exceeds all hope of description. But it is not only to be studied for its gorgeous profusion of suns—where in a short time many thousands pass before the eye—nor for the many beautiful pairs that it envelopes—such as the

5.

well-known β *Cygni*, with its elegant contrast; or χ (R.A. 19h. 42m. D.N. 33° 27′), inferior indeed, but very pretty; or the wide pair 61 (R.A. 21h. 1m. D.N. 38° 9′), whose parallax, the first well established, shows that they are nearer to us than the bright leaders of the constellation; or at the end of the right arm of the great cross, δ, whose minute comes at 1″·6 has proved such an annoyance to many a



6.

disappointed observer, who might however have succeeded in a twilight hour; nor again for its groups of irregular and artistic beauty; but for many peculiarities of arrangement, not altogether unrecorded, especially by Secchi, but scarcely adverted to as they deserve. Among the minuter stars, from perhaps the 8th to the 11th mag., configurations are not infrequent of such singular

regularity or peculiarity of arrangement that the idea of optical concurrence seems inadmissible. Triangles, squares, rhomboids, wreaths, festoons, coronets, indicate a collocation utterly inscrutable, but certainly not fortuitous. Such combinations are occasionally met with in other regions, but, as might be expected, are accumulated in the galaxy.

The glory of this sparkling zone, culminating in the splendours of *Cygnus*, is everywhere repeated in greater or less degree. *Aquila, Sagitta, Vulpecula, Lacerta*, to say nothing of more distant regions, all present fields of most gorgeous richness, which we must leave unnoticed. But before we finally cross this region to the other side, we must pause in *Vulpecula*, where, in R.A. 19h. 54m. D.N. 22° 23′, lies an especial mystery, the *Dumb-bell Nebula* (M 27). The search with the altazimuth will prove not difficult as guided by Diagram 2.

In mid-distance between *β Cygni* and *α Aquilæ* we we shall recognise a lengthened group of 4th and 5th mag. stars, the lowest in the figure, forming the constellation *Sagitta*. We may remark, in passing, that one of these, ζ, R.A. 19h. 44m., D.N. 18° 51′, is a very pretty wide double, the largest of which has been found by Alvan Clark, jun., to be an excessively close pair. Nearer to *β Cygni*, but to the left, is another less marked group, forming part of *Vulpecula*, close to one of the stars of which, in a rich field, we shall perceive two oval hazy masses in lateral contact, the nebula in question.

Like other objects of the same nature, this has been seen, or at any rate, drawn, in very dissimilar ways; it seems in fact almost inseparable from the character of nebulous light that its limits and gradations should be differently appreciated by different observers; and in this instance the additions resulting from larger apertures have almost obliterated the original idea; yet without suspicion of actual change. Minute twinklings are easily seen in the haze; and the Earl of Rosse finds a much greater abundance of stars than in the surrounding sky; yet he does not resolve it; and the spectroscope shows it as a huge mass of incandescent gas—apparently the little-comprehended element nitrogen.

Quitting now the galaxy for the region on its eastern side, we notice, a little above α Aquilæ, the familiar lozenge of *Delphinus* (a curious instance of configuration) the following or left-hand component of which, γ, is a noble pair of 4th and 7th mags. at nearly 12″, and somewhat differing in colour now, though Sir W. Herschel called them both white in 1779. Physical connection is inferred from an extremely slow relative movement; more decidedly from a motion through space common to both—an unsolved and insoluble mystery. South of γ, a little to the west is Σ 2725, a very pretty little couple, at 4″·2; possibly of binary character.

A little further south-east we shall find another less conspicuous group of small stars, chiefly in the form of a trapezoid. This is *Equuleus*. It is given in Diagram 3, where α is at the lowest angle.

Here γ, the 4¾ mag. star nearest *Delphinus*, forms a striking combination with one of 6th mag., and has itself been doubled by Knott with an 11 mag. comes at 2″·1. And beyond the limit of the trapezoid to the south-west we find a very fine triple, ε, R.A. 20h. 53m., D.N. 3° 50′, the two closest of which are a beautiful pair in slow rotation, whose distance, less than 1″, renders it an excellent test for a moderate aperture. The third star also appears to be physically connected with the others. λ, readily found by sweeping less than 3° north of the last, and a little east, is also well worth looking for: 6 and 6½ mags. at about 2″.

We shall now cross the border into *Pegasus*, the leader of which, in respect of position, ε, is represented in the same diagram; a bright yellow 2½ mag. star with 2 comites, 9 and 14 mags. Sweeping rather more than 2¼° north of this, about 14m. west (R.A. 21h. 24m., D.N. 11° 38′) we shall come upon M 15, a noble globular cluster, of similar character to M 13 in *Hercules*, but of smaller size. Sir J. Herschel gives the stars 15 mag. of his scale, running up to a central blaze, and more condensed there than according to the idea of equal distribution. It is not quite circular, and surrounded with outlying streams. Buffham, with a 9-inch "With" mirror, has detected a dark patch near the centre, and two faint rifts like those in M 13, traces of one of which I think I once perceived. This fine object deserves a long and steady gaze.

About 1° south of the cluster, a little west, we shall readily find a beautiful pair, perhaps slow binary, Σ 2799, both 6·6 mag. of Struve's scale, 1″·4 distant.

Ranging east and west, at some distance below *ε Pegasi*, we shall remark the subject of Diagram 4; part of *Aquarius*. At the east end a very remarkable pair, ζ, R.A. 22h. 23m., D.S. 0° 38′, will be found in the interior of an easily-recognised triangle of stars, not much differing in brightness. The magnitudes are given 4 and 4½; the distance 3″·6; the binary character is certain, and the period last assigned 1625 years. This is an excellent object for a small telescope, and will lead to many wondering thoughts as to the possible state of existence there. A much larger aperture will be required to secure Burnham's little pair, 8½ and 10 or 11 mag. at 1″·5, 11′ south of ζ.

To find our next object, M 2, R.A. 21h. 27m., D.S. 1° 22′, by sweeping, we must note its configuration in the diagram with α and β, two stars conspicuous for insulation in a dull region. It will repay the search, being, not indeed a brilliant, but a very interesting ball of several thousand very minute stars, 15 mag. of Sir J. Herschel, "a most superb cluster" in his reflector, "like a heap of fine sand," blazing in centre: D'Arrest sees it of irregular form. What an object, could we reach its neighbourhood!

But perhaps more surprising, though in quite a different way, is the next, H iv. 1—that is, No. 1 in Sir W. Herschel's fourth class—a noble specimen of what, from their equable light and defined edges, the illustrious discoverer termed Planetary Nebulæ. It lies in R.A. 20h. 58m., D.S. 11° 50′, and, to find it, we may carry a line through α and β nearly as far again, bending a little downwards: this will point out ν, a 5th mag. star, a little west of which we shall catch our object. It is tolerably bright, slightly elliptical, and of a pale blue tint. Lassell has seen a luminous well-defined ring in its interior; Buffham, with 9-inch mirror, an opening. The Earl of Rosse, besides many faint projections, finds a narrow ray on either side, making the whole a singular resemblance to Saturn with a very thin presentation of the ring. Yet here too is gas! and as it seems, nothing but gas! But whence? how? wherefore?

And now we pass to the left over a long and rather dull region from the triangle in *Aquarius* to the chief star of *Pisces*, at the extremity of the constellation, about 20° under the well-known three stars that mark the head of *Aries*. *α Piscium* with the head of *Cetus* east of it are shown in Diagram 5. It is a fine pair, 5 and 6 mags. at 3″·2, the tints of which, as well as the mags., have been described with greater discordance than can be easily explained. *α Ceti*, the next conspicuous star to the east, is a very beautiful specimen of a large orange star, with a blue companion at a little distance, the colour of which may possibly be due to contrast, or heightened by it: this might be ascertained by hiding the great leader behind the edge of the field. There is a pretty little pair near them. The next star to the right, γ, is a striking double, 2″·6 apart, 3 and 7 mags., yellow and blue (greenish, ruddy, or tawny to some eyes). Above and to the right of this is ν, 4½ mag., attended by a very minute companion, a glimpse star to Smyth, but much easier of late. Below ν, a little to the right, is δ, a line through which from α will point out a very remarkable variable, *o*,

or Mira Ceti, R.A. 2h. 13m. D.S. 3° 31'. This changes from 2 mag. to equality with a very minute companion in about 331d. 8h. 4m., but not without some uncertainty. Its colour, according to Sir J. Herschel, is a full ruby; I saw it so once, when about 10 mag., if it was the right star, but it was immediately clouded over: at another time, near *maximum*, pale yellow, without a trace of red. Flammarion also finds it by direct comparison less red than a gas flame. This tint would be an interesting object of study; but care must be taken in identification. Mira is now decreasing.

Having mentioned the head of *Aries*, we must recollect that γ, the smallest of the three stars, is a double, interesting as the first of these objects recorded by Hooke in 1664, and a fine object, nearly 9" distant. These three stars are introduced into this diagram as guides to *Triangulum* just above them, where we shall find our last two objects.

ι, R.A. 2h. 5m., D.N. 29° 44', topaz and green, an exquisitely coloured pair, $5\frac{1}{2}$ and 7 mags., distance 3"·5; perhaps in slow orbital motion. We shall pick it up about $\frac{3}{4}$° north of α, a little to the east. The other is a strange phænomenon,

M 33, R.A. 1h. 27m., D.N. 30° 4', about 1° north of α, and not far towards the west. Feeble as it is, it will be visible even with a very small aperture, from its great extent; fully $\frac{1}{2}$°, or the diameter of the moon, from north to south; but on the other hand may, from want of contrast, be imperceptible with any but a very low power. The elder Herschel thought it was resolved into the minutest possible stars; but this has not been confirmed. His son and d'Arrest find a principal condensation with subordinate nuclei and nebulous tracts; the Earl of Rosse, a flocculent and spiral structure, with curved intersecting branches; a strange, incomprehensible form.

Our space will not admit of an extension of this very meagre and imperfect selection, limited for the most part, for obvious reasons, to such portions of our autumnal sky as are rapidly passing away. T. W. WEBB

AN OBSERVATORY FOR HONGKONG

WE observe that Sir John Hennessy, the Governor of Hongkong, has succeeded in getting an item of twenty thousand dollars for an observatory and time ball passed by his Legislative Council in the estimates for the current year, in addition to a sum of ten thousand dollars voted for the same purpose last year. The advice of Major H. S. Palmer, of the Royal Engineers, has been sought by the Colonial Government, and in a valuable paper published in one of the most recent Government Gazettes, he details the advantages, imperial and local, which may be expected from a physical observatory in Hongkong. The favourable position of the island for certain observations, especially with regard to the typhoons of the China Seas, on meteorology generally, and on terrestrial magnetism, was first brought to the Governor's notice in September, 1879, through the Secretary of State for the Colonies, by Dr. Warren De La Rue, as Vice-Chairman of the Kew Committee of the Royal Society. He pointed out the extreme importance of obtaining accurate records of the magnetic and meteorological conditions of the China Seas. There are at present only four observatories at which continuous observations are taken on the eastern coast of Asia and the adjacent islands—one at Batavia, in Java, supported by the Dutch Government, one attached to the Russian embassy at Peking, one at Siccawei, near Shanghai, and one at Manila. The two last are supported by the Society of Jesus. It is pointed out that Hongkong divides the distance between Siccawei and Manila, and would consequently be a most valuable acquisition to the list. The support of the Government of the Colony for a limited number of years to an observatory provided with self-recording instruments is therefore invoked. English officials and merchants abroad do not as a rule display much interest in science, and it is therefore fortunate that the gentleman at present at the head of the Government of Hongkong is one capable of appreciating the great importance of Dr. De La Rue's suggestion and of energetically carrying it out. Governor Hennessy had indeed in some sense anticipated the request, for he had, two years previously, in the first estimates which he prepared for the colony, obtained five thousand dollars from his Council for an observatory and time-ball. He entirely agreed with Dr. De La Rue's remarks, and added that the clearness of the atmosphere at certain seasons would admit of a valuable record being made of sun-spots, while the tides and varying temperature of the seas surrounding Hongkong, and the slight but frequent earthquake phenomena, would also be deserving of the attention of competent observers. A sum of between thirty and forty thousand dollars has been granted altogether for the establishment of an observatory, the chief objects of which are—

1. To determine the local time by astronomical observations, and drop a time-ball daily.
2. To obtain a series of meteorological observations with instruments of the best kinds, and to acquire information relating to the typhoons and monsoons of the China seas.
3. To obtain a series of observations in terrestrial magnetism, also with the best modern apparatus.

In his report Major Palmer addresses himself to each of these subjects separately. He recommends, we are glad to notice, that none but the best instruments should be employed, and that the observatory records should be made and published with scientific precision, and be such as to command public confidence. The meteorological department, he points out, besides furnishing science with valuable data from a locality well suited for the observation and collection of facts appertaining to certain phenomena of special interest, cannot fail to have a direct and practical value by affording security, by its predictions and weather-warnings, to life and property in seas navigated by vast numbers of native and foreign vessels, but subject, during four or five months of the year, to rotatory storms of appalling violence and danger. Its operations, as well as its purpose, would be twofold. There would be the systematic observation and record of the ordinary phenomena of pressure, temperature, humidity, rain, sunshine, wind, and hydrometeors, such as are usual in observatories of the first order, and observations of atmospheric electricity. The second branch would be the observation and collection, as far as possible, of facts and phenomena relating to typhoons, both for the protection of marine interests and for the purpose of contributing bit by bit to our knowledge of a subject at present but little understood. He recommends that measures should be taken to enable the director of the observatory to be placed in prompt telegraphic communication with Manila, Amoy, Shanghai, Saigon, and Singapore, as well as with the south of Japan, and indicates the steps necessary for this purpose.

As for terrestrial magnetism, the character of the rocks and soil of Hongkong, and the neighbouring promontory of Kau-lung, is not, he thinks, the most favourable that could be chosen for magnetic research, yet the position of the colony on the magnetic chart, and with respect to other places where observatories are already established, leaves no room to doubt the value of well-conducted observations.

As to the staff of the observatory, a director, Major Palmer very properly suggests, should be obtained through the Astronomer-Royal, and thinks a salary of not less than 700*l.* a year should be given. Minor officers could be obtained among the non-commissioned officers of the Ordnance Survey Companies of the Royal Engineers. The prime cost he estimates at 6300*l.*, and the

subsequent annual charge at about 2000*l*. It would seem therefore that we may shortly expect to find a tolerably complete and well-equipped observatory in the most eastern of our possessions. It is believed also that, with the assistance of Mr. Hart, the Inspector-General of Chinese Customs, the Government of China may be induced to establish a series of meteorological stations at various points on the seaboard of their vast territory. A perusal of Major Palmer's report leaves on our mind the impression that the Colonial Government is fortunate in being able to obtain at the present time the advice and co-operation of an officer of his ability and scientific attainments.

PROBING BY ELECTRICITY[1]

THE instrument[2] I have the honour of presenting to the Academy has for its object the determination of the exact place occupied by balls of lead, fragments of shell, or metallic substances of any kind embedded in the body of a person wounded by firearms; and it may be considered as a form of the well-known induction-balance of Prof. Hughes.

This exploring instrument enables us to determine that position for the most part with very great exactness, and that without any pain to the patient, which is not the case when we use metallic probes, which require to be brought into direct contact with the projectile.

The instrument is composed essentially of a system of two parallel flat coils partially superposed upon one another in such a manner that the edge of one is nearly over the axis of the other (Fig. 1). One of these coils

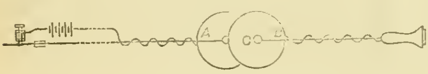


Fig. 1.

(A) is made of thick wire constituting a portion of the primary circuit, and the other (B) of thin wire, constituting a portion of the secondary circuit. Both coils are imbedded in a mass of paraffine placed in the interior of the wooden case furnished with a handle.

A vibratory current from a galvanic battery traverses the primary coil, and the secondary circuit includes an ordinary telephone. Under these circumstances no sound is heard from the telephone; but if we cause any metallic body to approach the part (C) common to the two coils, the silence immediately gives place to a sound the intensity of which will depend upon the nature of the metallic body, upon its form, and upon its distance. We may remark in this connection that the most favourable form that can be assumed by the projectile for which we explore, is that of a flat disk with its face parallel to the surface of the skin, and that the most unfavourable, a similar disk with its face perpendicular to the same surface.

It is difficult in practice to obtain the exact adjustment of the coils required, and it is therefore found advisable to introduce into the primary and secondary circuits respectively two other coils (D and E, Fig. 2) analogous to the first, but very much smaller, whose common surface can be modified by the play of a micrometer screw.

By means of this fine adjustment we are able easily to reduce the telephone to the most complete silence. It should be added that the effects obtained when a condenser (F) is introduced into the primary circuit are much inferior to those obtained without, as had been independently predicted by Prof. Rowland of Johns Hopkins University.

If we wish to ascertain the depth at which the metallic mass lies embedded this is easily ascertained if we know *à priori* its form, its mode of presentation, and its substance. It is only necessary to adjust the apparatus to

Fig. 2.

silence while it is applied to the skin, after which, removing the apparatus, we bring near it another metallic mass similar to that explored for, so as to reproduce silence anew, and the distance of this mass from the exploring instrument gives the measure which it is desired to determine.

I conclude this Note by the relation of an experiment made in the office of Dr. Frank Hamilton of New York, on October 7 last, in the presence of thirteen eminent surgeons.[1] The experiment was made upon the person of Col. B. F. Clayton, wounded in 1862. The ball entered in front through the left clavicular articulation, breaking the clavicle. Doctors Swineborne and Vanderpool supposed that it was lodged under the scapula, but my apparatus demonstrated, on the contrary, that it was located in front and just below the third rib.

MAGNETIC SURVEY OF MISSOURI

IN NATURE, vol. xxiii. p. 583, the writer presented a chart of magnetic declination which represented the results at forty-five stations in Missouri. The facts seemed to indicate a marked effect due to contour. Up to the middle of August of the past summer nothing inconsistent with this explanation was found, although the number of stations had been increased to over eighty. By that time the stations had become so numerous in Central Missouri that a more minute survey along the river bank between Jefferson City and Glasgow gave promise of affording a crucial test. It was necessary that the 8° line, which bends down the river, crossing at some point east of the mouth of the Osage River, should *return* on the south side of the river, looking something like a reversed contour line.

What we did find was, that the 8° line crosses the Missouri Valley *without bending*, running south-west to near the summit of the "divide" between the Osage and Missouri rivers, and *then* bends abruptly to the north-east, re-crossing the Missouri above Jefferson City, and

[1] Upon an Apparatus for Determining without Pain to the Patient the Position of a Projectile of Lead or other Metal in the Human Body. Note by Prof. Alexander Graham Bell, read by M. Antoine Breguet at the Paris Academy of Sciences. Contributed by the Author.

[2] This instrument has originated from researches undertaken in the Volta Laboratory at Washington on the occasion of the sad attempt upon the life of President Garfield. This Note is preliminary to a paper which I shall publish shortly, giving a complete account of these researches. So many different persons have been kind enough to give me the benefit of their suggestions and advice concerning the method of exploration for this object, that I can only mention here the names of a few: Prof. Hughes, George M. Hopkins, Sumner Tainter, Thomas Gleeson, Dr. Chichester A. Bell, Charles E. Buell, Prof. Simon Newcomb, Prof. H. A. Rowland, M. Rogers, Prof. John Trowbridge, J. H. C. Watts, the director of the Western Union Telegraph Company at Washington, and the correspondent of the *New York Tribune* at Washington.

[1] Doctors G. H. Gardner, G. Durant, Ed. Bermingham, N. Bozeman, L. Damainville, J. N. Hinton, Francis Delagield, F. H. Hamilton, D. Chamberlain, Elias Marsh, J. G. Johnson, Joseph Halderson, and J. G. Allan.

after a wide *détour* re-crosses east of Hermann, returning to the south-west, thus forming an immense cape-like area of maximum declination to the east of Jefferson City. It is therefore improper to regard the chart referred to as more than a representation of observations then made, although the stations were more numerous than is usually deemed necessary for an area of 60,000 square miles.

The area of minimum declination represented on the chart of April 21 has been more satisfactorily outlined, and a closed area of maximum declination lying to the west has been determined with certainty.

The work of the past summer has therefore increased the complexity of the isogonic lines, and the *gradual* change in declination in passing through these areas of abnormal value shows that the causes must act over areas of from 1000 to 3000 square miles, *i.e.* that the observed effect is not due to minute local causes at the several stations. It will not be possible to determine fully the extent of these abnormal influences until similar work done in adjoining States shall enable a more precise determination of *normal* values. The stations of observation in Missouri now number over 100. Arrangements for the summer of 1882 have already been made, and the survey will be carried forward on a still more extended scale.

FRANCIS E. NIPHER

St. Louis, October 8

THE ECHINOIDS OF THE "CHALLENGER"

ZOOLOGISTS in general, and echinologists in particular, will welcome vol. iii. part 9 of the "Report on the Scientific Results of the Voyage of H.M.S. *Challenger*," which has just been published. It deals with the Echinoidea, and has been prepared by Prof. A. Agassiz, a more competent reporter than whom it would be difficult, if not impossible, to find. We do not propose to do more than give a brief outline of the principal results brought to light in this portly volume, which runs over some three hundred pages of text, and is illustrated by sixty-five plates.

Commencing with a few remarks on classification, Prof. Agassiz passes on to treat at more length of that vexed question of the position of the axis of the Echinoidea. He dissents from the theory put forward by Lovén in his "Études," a memoir which, however much one may differ from it, cannot be read without a feeling of admiration of the "infinite skill"—to quote Prof. Agassiz's happy expression—displayed by the author. Our reporter again asserts the position he has all along held, that, judging from embryological data, the position of the axis is in the main determined by that of the madreporiform plate. Next in order he deals with the structure of the coronal plates, the anal system, the fascioles, and the structure of the spines. In connection with the latter subject Prof. Agassiz takes exception to some views which we have elsewhere put forward as to the systematic value of acanthological characters. His opinions on any point of Echinoid structure merit the highest respect, and so we do not propose to enter here into an examination of his criticism on our work—a criticism, be it said, which is conceived in the true scientific spirit. A more fitting opportunity will offer itself in a further communication on the subject with which we are at present engaged. The reporter then goes on to notice with extreme aversion the attempts to construct "genealogical trees" "which have become so fashionable." In spite of Prof. Agassiz's well-earned reputation, however, one reads with a sort of shudder the assertion that he is about "to show once for all how futile it must be to carry on" these attempts, especially when we remember the men of mark who engage in them. But a genealogical tree is a upas tree to Prof. Agassiz, and he attacks it with hearty good will, albeit we think that the mathematical axe which he wields is by no means so destructive as he appears to believe. That relations exist between the different groups of Echini no one knows better than Prof. Agassiz, and in the next two or three sections of his Report he shows how well he can use his knowledge in the interesting connections he traces between recent and fossil Urchins, and since this relation does exist we cannot see why the attempt to indicate it graphically or descriptively is to be condemned as futile, even though there may be a minimum of 2^{19} possible combinations of variables. Having passed in review the relations between recent and fossil Echinoids the reporter then comes to what is the real sum and centre of his Report, the description of the species and genera, and here we have an abundance of most interesting matter.

The *Challenger* Expedition has added fifty-two new species, comprised in fifteen new genera, to our list of Echinoids, a very considerable addition when we remember that the order is a comparatively small one. The group which has been most largely increased is that of the Echinothuridæ, of which twelve new species have been described, whilst of the Echinometridæ, Clypeastridæ, and Spatangina only previously known forms have been obtained. It would be of course out of the question to notice all the interesting facts brought to light here; the Report itself must be read for this, and we are fain to content ourselves with a few passing remarks on some of the more striking forms. The remarkable genus Asthenosoma, which was established by Grube in 1867 (Calveria, Wyville Thomson, 1869) to contain an Urchin with a flexible test has been increased by the addition of five new species with a very varied bathymetrical range, one having been obtained at 10 fathoms and another at 1400. Wyville Thomson's genus, Phormosoma (1874), has afforded seven new and most interesting species, inhabiting, as a rule, deeper water than its companion genus (255 fathoms to 2600 fathoms). To this genus belongs the honour of furnishing the largest Urchin which Prof. Agassiz has hitherto met with, *Ph. hoplacantha*, Wy. Thoms., measuring 312 mm. in diameter—truly a good-sized specimen. Amongst the Didematidæ we have a remarkable new genus, Aspedodiadema, with the abactinal system and ambulacral plates of a Cidarid combined with the thin test and hollow spines of a Diadema. Micropyga is another hitherto undescribed genus of the same family. Passing over the Echinometridæ (no new species), the Temnopleuridæ (three new species), the Triplechinidæ (one new species), and the Clypeastridæ (no new species), we notice amongst the Petalosticha thirteen new species of the curious genus Pourtalesia (A. Agass., 1869) with its remarkable beaked test; and, amongst other new genera, Cystechinus, which appears to be related to the fossil genera Galerites and Ananchytes. We might go on for a long time noting one interesting form after another, were it not that to do so would make this notice inordinately long. How far further study and discovery will affect the number of genera and species enumerated here it is impossible to say, but as Prof. Agassiz is by no means given to multiplying species, and as most of the specimens appear to have been well preserved—only a few having been described from fragments—it is likely that the greater number will stand. A word in conclusion as to the plates. The majority of them have been drawn by Mr. Roetter, and we congratulate Prof. Agassiz on having at his disposal the services of so gifted a draughtsman. Many of the plates are to our mind very gems of lithographic art. The drawings of the sections of spines, though very pretty, and in most instances handled with great delicacy and finish, do not always give the clearness of detail that could be desired, and the mechanical arrangement both of these plates and of those containing the pedicellariæ and the side views of spines is decidedly objectionable. It may be that Prof. Agassiz and his

artist have constructed some subtle key whereby they can discover at once the position of any required figure, but it is hidden to our clumsier intellect; and when a plate contains from thirty to fifty-nine figures, numbered apparently without any definite order, the task of picking out any given figure becomes rather tedious. Having said this, however, we have said all that we think we can say against the beautiful plates which accompany Prof. Agassiz' most interesting "Report on the Echinoidea of the *Challenger*." H. W. MACKINTOSH

NOTES

THE anniversary meeting of the Royal Society will be held, as usual, on St. Andrew's Day, the 30th inst. The following is the list of the Council and Officers nominated for election:—President, William Spottiswoode, M.A., D.C.L., LL.D.; Treasurer, John Evans, D.C.L., LL.D.; Secretaries, Prof. George Gabriel Stokes, M.A., D.C.L., LL.D., Prof. Michael Foster, M.A., M.D.; Foreign Secretary, Prof. Alexander William Williamson, Ph.D.; other members of the Council, Francis Maitland Balfour, M.A., I. Lowthian Bell, F.C.S., Sir Risdon Bennett, M.D., Prof. Thomas George Bonney, M.A., Prof. Heinrich Debus, Ph.D., Alexander John Ellis, B.A., Sir John Hawkshaw, M.I.C.E., Thomas Archer Hirst, Ph.D., William Huggins, D.C.L., LL.D., Prof. Thomas Henry Huxley, LL.D., Prof. Joseph Lister, M.D., Prof. Daniel Oliver, F.L.S., Prof. Henry Enfield Roscoe, B.A., LL.D., Warington W. Smyth, M.A., Henry Tibbats Stainton, F.G.S., Edward James Stone, M.A. Prof. Huxley having retired from his office as one of the secretaries, as we intimated last week, Dr. Michael Foster has been named in his stead.

THE Treasury has, it is stated, awarded the late Astronomer-Royal, Sir George Airy, a pension of 1100*l*. per annum, in consideration of his long and valuable services.

MOST of our readers will have heard with regret, and probably surprise, that Prof. Ferrier has been charged with a breach of the Vivisection Act. On the general question our opinion is well known, but into the merits of this particular case we cannot enter so long as the trial is pending.

THE Queen has conferred the honour of Knighthood upon Mr. Erasmus Wilson, President of the Royal College of Surgeons.

THE death is announced of Dr. Bouillaud, the *doyen* of medical science in France, and Member of the Academy of Medicine and Academy of Sciences. He was born at Angoulême in 1796.

THE impending change in the French Cabinet has brought forth an unusual number of regulations from the Minister for Public Instruction. Two of the more notable are the creation at Limoges of a Government school for industrial arts and a general reorganisation of the veterinary schools of Alfort (near Paris), Lyons, and Angoulême.

M. KELLER, who is a Member of the French Senate, has met with an accident in his laboratory. His hand has been severely burnt by an explosion, and he will probably not be able to resume work for a month.

THE experiments at the Paris Opera with the electric light have been successful so far as concerns incandescent light, which is now regularly used. A final decision on the matter will be come to very shortly.

OUR Paris Correspondent writes that the success of the Siemens Electrical Railway has been so great that the Municipal Commission appointed to report on the possible application of electricity will advise the experiment of an elevated railway in some part of Paris. The only objection to the erection of such a line on the Boulevards is its aspect, which it is supposed will not be sufficiently ornamental. A large number of practical suggestions will be made by this Commission.

THE Russian Government has made a grant of 14,000 roubles for next year for two Polar observing stations:—One at the mouth of the Lena, and the other, of second rank, but also for meteorological and magnetic observations, on one of the islands of New Siberia.

THE Corporation of Chesterfield deserves credit for their enterprise; they have decided to dispense with gas entirely as far as public lighting is concerned, and to replace it with the electric light. The lighting will be done by means of about twenty-two Brush "arc" lamps and about seventy Lane-Fox incandescent lamps. Doubtless the example of Chesterfield will soon be followed by other towns.

THE Council of the Society of Arts, on the recommendation of the judges in the late competition of plant labels, are prepared to renew the offer of a Society's silver medal, together with a prize of 5*l*., which has been placed at their disposal for the purpose by Mr. G. F. Wilson, F.R.S., for the best label for plants. The object of the offer is to obtain a label which may be cheap and durable, and may show legibly whatever is written or printed thereon; the label must be suitable for plants in open border. These considerations will principally govern the award. Specimen labels, bearing a number or motto, and accompanied by a sealed envelope containing the name of the sender, must be sent in to the secretary of the Society not later than May 1 1882.

THE Royal Commission on Technical Instruction, presided over by Mr. Samuelson, M.P., has begun its work in Paris by visiting the École d'Apprentis in the Boulevard de la Villette, the École d'Horlogerie in the Faubourg du Temple, and those communal schools in which handicrafts are taught. After inspecting the secondary and higher technical schools of Paris the Commissioners will proceed to Chalons, Lyons, Rouen, and some manufacturing towns in the North of France.

AT the ordinary meeting of the Council of the Sanitary Assurance Association, held at the offices, 5, Argyll Place, Regent Street, on Wednesday, October 26, Prof. Hayter Lewis, F.S.A., in the chair, certificates were issued under the Corporate Seal of the Association to those subscribers who had carried out the recommendations of the Association with regard to the sanitary arrangements of their houses. These certificates, which are as yet a new feature in connection with provident householding, are not of less importance than Fire Insurance polices. The certificates are signed by the chief sanitary officer of the Association, Prof. Corfield, M.D., and the surveyor, Mr. Mark H. Judge, and they guarantee the satisfactory condition of the houses to which they refer; the inspection, report, and supervision of the work, where alterations are necessary, being made personally by both officers. The certificates are issued subject to an annual inspection of the property, for which the members are charged a small fee, according to the rateable value of the houses; for instance, for a house rated at 80*l*. the fee is half-a-guinea for each annual inspection, while for a house rated at 200*l*. the fee is two guineas. Detailed reports of works in progress were made, and correspondence thanking the Council for the thoroughness of the reports and supervision of work was read. It is just twelve months since the first meeting of the Association was convened, under the presidency of Sir Joseph Fayrer, K.C.S.I., to form an organisation which should apply the combined sanitary knowledge and experience of medical men, architects, and others by means of specially qualified officers who should yearly inspect the houses of members and report upon their drainage, water supply, and ventilation. The Association was soon after incorporated by special licence of the Board of Trade, by which it is bound to apply the whole of the income and property of the Association solely towards the promotion of its objects, and no dividend or profit can be paid directly or indirectly to the members. The work of the Associa-

tion is very simple in plan. Application is made for the inspection of a house, and the inspection is made personally by both the chief sanitary officer and the surveyor, who supply a detailed report on the sanitary condition of the property, together with a specification of the work necessary to put it into a condition satisfactory to the Association. While this work is in progress it is supervised by these officers, and on its completion the Council grant a certificate guaranteeing the sanitary condition of the property, subject to an annual inspection by the officers of the Association.

AT an examination held by the Sanitary Institute of Great Britain on November 3 and 4, eight candidates presented themselves, and the Institute's Certificate of Competency as Local Surveyor was not awarded, but the Institute's Certificate of Competency as Inspector of Nuisances was awarded to J. Horrocks, W. Sortwell, and J. W. Witts.

THE Linnean Society of New South Wales has had the enterprise to organise a course of lectures on zoology, open to all who care to take advantage of them. They begin on October 4, and are to extend to December 9, about two lectures being given each week. The lecturer is Mr. W. A. Haswell, M.A., B.Sc.

IT is announced, we learn from the *Lancet*, that the three volumes of the *Transactions* of the International Medical Congress will be published and ready for distribution at the beginning of December. To non-members the price of the work will be 30*s*., and the volumes can each be bought separately. The first volume will contain the list of members, accounts of the general meetings, the general addresses, the description of the specimens exhibited in the museum, and the transactions of the sections of anatomy, physiology, pathology, and materia medica and pharmacology. Volume II. will contain the transactions of the sections of medicine, surgery, State medicine, military medicine and surgery, obstetric medicine and surgery, and diseases of children. Volume III. will contain similarly the transactions of the sections of ophthalmology, mental diseases, diseases of the skin, diseases of the throat, diseases of the ear, and diseases of the teeth. Orders for the work will be received by J. W. Kolckmann of Langham Place.

BULLETIN No. 6 of the United States Entomological Commission consists of a General Index and Supplement to the nine Reports on the Insects of Missouri, by Prof. C. V. Riley, forming in itself a volume of 177 pages. It is very complete. All the descriptions of new species described in the Reports are reproduced, with such alterations indicated as time may have rendered necessary. It is carefully analytical, and one heading will strike many as introducing a comparatively new term, *i.e.* the "List of descriptions of the *adolescent* states."

WE have already referred to the Smithsonian Report for 1879. Mr. O. J. Mason's bibliography of Anthropological Investigations, which appears in the Report, has been separately reprinted, and will be found useful by those interested in the subject.

DR. OTTO FINSCH, whose scientific journey in Polynesia we have repeatedly referred to, arrived at Wellington, New Zealand, in June last, and now intends returning soon *viâ* Sydney.

THE additions to the Zoological Society's Gardens during the past week include a Tiger (*Felis tigris* ♀) from Assam, presented by Col. Owen Williams, M.P., F.Z.S.; a Black Bear (*Ursus americanus*) from North America, presented by Capt. McPherson, barque *Ocean Nymph*; two Common Polecats (*Mustela putorius*) from France, presented by M. P. Pichot; a Young Ostrich (*Struthio camelus*) from Africa, presented by Mr. William Jewram; a Great Eagle Owl (*Bubo maximus*), European, deposited; three Common Curlews (*Numenius arquata*), two Red-throated Divers (*Colymbus septentrionalis*), European, received on approval.

OUR ASTRONOMICAL COLUMN

DOUBLE-STARS.—An important series of observations of double-stars has been recently issued from the United States Naval Observatory at Washington. It includes all the measures made by Prof. Hall with the 26-inch refractor from 1875 to 1880, and a few in the year 1863 with the 9·6-inch equatorial. There are observations of double-stars selected by M. Otto Struve for the comparison of micrometrical measurements by different astronomers, which remain for discussion when those of other observers are published. In addition, in order to apply a geometrical test to the observations, Prof. Hall has carefully measured the multiple stars Σ 2703 and 311, and the stars in the trapezium of Orion. The observations have been made with the filar-micrometer by A. Clark and Sons, which is commonly used with the large equatorial. Then follow measures of objects chiefly taken from the catalogues of the Struves, with a few others mostly discovered by Mr. Burnham. Σ 2 was not separated with power 888 in 1879. Of γ^2 Andromedæ we find the angle 101°·0 distance 0″·358 for 1878·21; 40 Eridani (B.C.), 125°·0, 3″·515 for 1879·18. A great change is shown in O.Σ. 82; we have 230°·8, 1″·08 for 1848·67, while Prof. Hall's measures give 182°·25, 0″·765 for 1879·16. Mr. Marth's faint companion of Sirius, estimated 13m., was at 114°·9, 71″·4, at the epoch 1847·47, which, compared with the particulars at p. 38 of *Memoirs* R.A.S., vol. 36, indicates fixity. Prof. Hall remarks on the supposed companions of Procyon, "I have never been able to see any of these companions that would stand the test of sliding and changing the eyepiece, turning the micrometer, &c., and am therefore doubtful of their existence. This is an interesting star for the powerful telescopes of the future." Six nights' measures of 25 Canum Venat. give 157°·5, 0″·507 for 1879·49; Dr. Doberck has calculated elements for this star, period 124½ years. γ Coronæ Borealis was single in 1875-76 and 1879. 72 Ophiuchi was examined in 1876 and 1879, but no close companion was visible: it may be remembered that at the epoch 1859·61 Secchi saw and measured the close star, and recorded it as "*bene separata*," and Otto Struve has measures of it in 1842, 1847, 1851, and 1876, those in the latter year corresponding almost precisely to the date of the Washington examinations, which seems to point to optical illusion, unless rapid variability is admitted. At the epoch 1879·77 δ Equulei was thought to be elongated at 150°, but Prof. Hall was not certain of its duplicity. Many of the more interesting binaries are included in this series of measures. The observations of the companion of Sirius made at Washington from 1866 to 1879 are given in a collective form, and we have observations of the faint stars near the annular nebula in Lyra, of which the following results possess value; *a* is the brightest of these stars and the one near the following end of the nebula; the angles and distances are referred to it except in the case of the companion of the triple star *f*, which are referred to *f* itself:—

		Pos.	Dist.	Magnitudes.
		°	″	
a and *b*	1877·582	225·50	93·90	10 and 14
a ,, *c*	1877·582	268·00	115·84	10 ,, 13–14
a ,, *d*	1877·592	286·90	138·58	10 ,, 12–13
a ,, *e*	1877·592	292·60	122·90	10 ,, 12
a ,, *f*	1877·582	313·70	101·79	10 ,, 13–14
a ,, *g*	1877·592	350·60	77·18	10 ,, 13
f ,, f_1	1877·592	253·30	3·96	13–14 ,, 13–14
f ,, f_2	1877·592	4·80	17·32	13–14 ,, 14–15

To connect the nebula with the stars the following estimates were made:—

(1) The right line *a* to *b* is 11″ outside of the nebula.
(2) ,, ,, *a* ,, *c* very nearly bisects the darker, interior part of the nebula.
(3) ,, ,, *a* ,, *f* is very nearly tangent to the nebula.
(4) ,, ,, *b* ,, *c* is nearly tangent to the nebula.

It is added that during these observations no star was seen inside the above ring of stars, nor any star within the nebula itself. Afterwards it was thought that a star was seen within the nebula, but Prof. Hall was not able to measure it.

GEOGRAPHICAL NOTES

THE twenty-third and twenty-fourth parts of the *Mittheilungen der deutschen Gesellschaft für Natur und Völkerkunde Ostasiens* contain an article by Dr. L. Döderlein on Oshima, one of the

largest of the chain of islands which runs from the south coast of Japan to the east coast of Formosa, and which include the Loochooan archipelago. The island has never before been visited by a European, and presents many features of scientific and general interest. Dr. Döderlein spent sixteen days there, during six of which he was kept indoors and in darkness by a violent typhoon, which is described in the twenty-third number of the *Transactions* of the same Society by Mr. Knipping of Tokio. Two distinct types of people were found in the island, one pure Japanese, the other—probably the original inhabitants before the Japanese conquest—are about the same size as Japanese, but somewhat better built. The face is not so broad, and grows smaller towards the bottom, so that the chin is pointed, a feature rarely found in the Japanese, whose chins are broad and round. The lips and nose are thin, the bridge of the latter being convex. The eyes are large like those of the people of Southern Europe. The most striking portion of the appearance of this people, however, is the thick hair which they have all over their bodies. In this respect they closely resemble the Ainos of Yezo and Saghalin. The language, of which some examples are given, is evidently a dialect of Japanese, half-way between the latter and Loochooan. The customs are in many respects different from those of Japan. The women tatoo themselves on the backs of the hands (the Aino women, it will be remembered, tatoo the lips) from the wrists to the roots of the nails. The marks are always the same, but no explanation of the custom could be given by the people. When a girl reaches the age of thirteen the operation is performed on her hands by people specially trained for the purpose. Married women never blacken the teeth, as in Japan. Although the population is about 50,000, there is neither priest nor temple in the island, and the people know nothing of a deity to whom they should pray. They pay a sort of veneration to their ancestors, but only to individuals, not to the progenitors of their race or tribe, as in Japan. Life would run very smoothly with the people, were it not for a poisonous snake, called *habu*, belonging to the Trimeresurus class. It attains a length of six or seven feet, and is equal in venom to the most poisonous snakes. The Japanese fear to land on the island on account of these reptiles, which are found everywhere. They are said to pursue eels in the streams, to climb trees easily, and even to do so for the purpose of attacking travellers more easily. At night no one will stir abroad, for the bite is invariably fatal unless assistance is immediately procured. In one place a village of thirty-one houses was abandoned because the *habu* were numerous in the neighbourhood. The only cure employed is excision of the part, or even of the limb, which has been bitten. The general conclusion at which Dr. Döderlein arrives is that Oshima belongs in its *fauna* to the Loochoos, and has but little connection in this respect with Japan. He thinks, therefore, that the boundary between two great zoological regions, the paleoarctic and the oriental, lies between the island and Japan.

In the last number of the *Proceedings* of the Berlin Geographical Society Dr. G. Fritsch has an extremely suggestive paper on geography and anthropology as mutual helpmates. The writer dwells upon the great aid each of these studies might derive from the sister science, if conducted in a broad and enlightened spirit. There are problems connected with the evolution of man and with his present distribution over the earth's surface, the solution of which depends upon a more exact knowledge of the former distribution of land and water, especially in the Tertiary period. The gap that separates man from any of the living anthropoids is profound; but it may possibly be bridged over or contracted to smaller proportions by the future discovery of fossil remains in the tropical regions, where the race most probably originated. Should these regions fail ultimately to yield the connecting links, then the conclusion would be strengthened that the evolution of mankind took place in some now submerged land, as, for instance, in the Lemuria of the Indian Ocean, or in the vast continent of which the Pacific islands may be regarded as the fragmentary remains. In the latter case the problem would remain practically insoluble, and the descent of men from some now extinct anthropoid forms would have to be regarded as at most an assumption incapable of strict demonstration. The present distribution of mankind, the writer goes on to point out, is largely bound up with more partial modifications of the earth's surface. A good instance is the Dravidian or aboriginal race of the Deccan, differentiated from the other types of the Asiatic mainland during the period that Southern India was still a triangular insular mass, before the now connecting Northern plains were created by the alluvia of the Indus and Ganges. From considerations of this sort Dr. Fritsch suggests a scheme of fundamental human types differing in some respects from any hitherto proposed by anthropologists, and insists especially on the necessity of separating the Koi-Koin (Hottentots and Bushmen) from the Negro proper. He also argues on similar grounds for the unity of the "homo Americanus," whom he refuses to regard as a mere branch of the Mongol or any other type of the Old World.

In a letter from Landana Père Carrie announces the arrival of Père Augouard's Stanley Pool expedition at Isangila on July 12. They were to resume their march for Manyanga on July 14, and hoped to reach it in eight days. Mr. Stanley is said to be hurrying on with his work in view of the expiry of his engagement with the International Association in March next.

The chance of obtaining news of the missing *Jeannette* exploring expedition before the winter closes in appears to be getting very remote. The revenue cutter *Thomas Corwin* has returned to San Francisco, and the steamer *Alliance* to Halifax, N.S., without any intelligence whatever of the party, and now we hear that the visit of the *Rodgers* to Wrangel Land has also been without result. Small boats belonging to the *Rodgers* circumnavigated Wrangel Land. The party in the boats also surveyed different parts of the island. The views from the top of the mountain on Wrangel Land disclosed sea all around it. The season had been most favourable for the purposes of exploration, owing to the openness of the navigation. The *Rodgers* would probably take up her winter quarters at St. Lawrence Bay, whence she expected to sail in June next, and proceed as far north as possible. Lieut. Berry finds that Wrangel Land is an island sixty miles in length.

The November number of *Petermann's Mittheilungen* is mostly occupied with two papers—On the Water-ways of France, by H. Keller; and on the Marsh Region of the Equatorial Nile System and its Grass Barriers. The latter is a paper of great value and interest, giving the results of the writer's observations during his recent terrible Nile journey. It is accompanied by a map of part of the Bahr el Abiad and Bahr el Seraf. There is also in the number a summary of the proceedings of the recent Venice Congress.

The Geographical Society at Bremen has received a telegram from the Brothers Krause, dated the 6th inst., announcing their safe arrival at San Francisco with good scientific and ethnographic collections. These explorers had visited the Chukchi Peninsula at various points, and intended spending the winter in the north of Alaska.

SCIENCE IN NEW SOUTH WALES

A GOODLY record of scientific work is furnished from time to time by our vigorous colonies on the Australian continent, where (as in other young countries), if the aids to science are not so complete as in some parts of Europe, the incitements to philosophical observation of natural phenomena are, for obvious reasons, peculiarly strong.

The *Journal and Proceedings* of the Royal Society of New South Wales for 1880, recently received by us, includes, with other matter, many valuable observations adding to a knowledge of the country. We gather that within the last quarter of a century, from natural decay, ring-barking, and clearing for cultivation, at least one half of the timbered land of the colony (it is estimated) has been denuded of trees. A very considerable diminution of rainfall might perhaps have been expected in consequence, but this has certainly not been the case; indeed statistics rather indicate the reverse. The principal rivers, too, have not been diminished in volume of water. Instructive in this connection is the experience of Mr. Abbott, with ring-barking of trees on his run at Glengarry. This operation (for improvement of grazing capacity) he carried out in 1869 and 1870, on most of the watershed of three creeks, each about two miles long, draining well-defined valleys shut in by high ridges of basalt. For twenty years previously these creeks were dry watercourses, only holding water for a few days after rain, and in a few places in winter. But soon after ring-barking they became, and have continued, permanent streams, with increased flow of water and number of springs. The explanation Mr. Abbott offers is that the large proportion of the rainfall formerly taken up by the gum-trees and evaporated, now finds its way to the creeks and rivers.

The records of thunder and hailstorms in New South Wales up to the end of 1878 were examined by Mr. H. C. Russell, with reference to the risk from hail to the Exhibition Building erected in 1879. The list is given in this volume. Mr. Russell could not trace any period in those storms, except that they seemed more numerous in the first year after a drought. They are not severe or numerous in wet years. The great number of storms when the earth is passing through the November meteor stream is noted.

The so-called salt-bushes of Australia are known to have properties that are of great advantage to sheep, which relish and fatten on the food, especially in times of drought. Mr. Dixon has analysed some eight of those fodders of the Riverina district, and shows, by comparison with well-known European fodders, that they stand well as to nutritive value. One is struck with the extraordinary amount of ash. In seven of the eight, the average ratios of total ash, potash, and common salt to digestible matter (oil, carbohydrates, and albuminoids), taken as 100, are 47, 9·538 and 7·689 respectively; and the difference here from European fodders is conspicuous. Cotton bush (the eighth examined) ranks with the latter. Only two contain a very large proportion of common salt, viz. oldman salt bush (the most prized by graziers), has 15·403, in the relation just specified, and small salt bush, 14·590. While digestion is doubtless promoted by the soluble chlorides, it is in the wool that the greatest effect of the diet (so rich in potash) might be expected, and the high esteem in which Riverina wool is held, is a verification of this.

Various kinds of coal of New South Wales have been subjected to analysis by Mr. Dixon and by Prof. Liversidge, the latter of whom specially wished to see how they compared with our coals. He found the Northern District coals to contain least ash, average percentage 4·61; those of the Western District have 10·44 per cent.; and those of the Southern 10·99. Thus some of the Northern coal is quite equal in this respect to the Welsh and Scotch coals, and but little inferior to the English Newcastle coal. The quantity of sulphur in New South Wales coal is by no means excessive. Prof. Liversidge also furnishes an account of some minerals from New Caledonia, including the nickel-bearing *Noumeaite*. This mineral seems to be completely amorphous; the mass splits up into smooth concave-convex pieces like petals of an unopened bud. It is in some cases soft and brittle, and in others hard and tough enough to be cut into ornaments. The colour varies from the palest tinge of green to full rich malachite green. The composition ranges from practically pure hydrated silicate of magnesia to what is also practically only hydrated silicate of nickel. The earthy cobalt ore (asbolite) from New Caledonia differs considerably from those met with in other places; baryta is entirely absent, but magnesia seems to have taken its place in some cases.

An interesting paper by Dr. Manning, medical superintendent of the Hospital of the Insane at Gladesville, treats of the causes of insanity in 3077 patients admitted to that institution in ten years from 1869; a comparison being also drawn with English statistics. We note that 3·9 per cent. of the cases of insanity are attributed to isolation and nostalgia conjointly (a category not given in the English table). The cases of pure nostalgia were those of foreigners, who spoke English most imperfectly. The cases of isolation included shepherds, whose occupation some years ago was most lonely, and still is, in some places, though the state of things is improving in this respect. Dr. Manning found last year that more than one half (1038 out of 2036) of the inmates of those institutions in the colony were apparently quite friendless, and that 10 per cent. were foreigners. The isolation, which is something terrible to a new emigrant, and which lasts often for years, is kept up by the disparity of the sexes, which at the close of 1879 stood at 409,665 males and 324,617 females, and it is fostered by the peculiar shifting and restless life of the miners and the bushmen. Dr. Manning thinks the insanity from intemperance has been exaggerated; the percentage at Gladesville is 8·3. The vile quality of the drink (he considers) and the system of drinking (short reckless outbursts, with prolonged periods of abstinence), are prominent factors in the result. Sunstroke, as might be supposed, causes insanity to a much greater extent in New South Wales than in England; 5 per cent. of the cases are accredited to it. Dr. Manning also expresses the opinion that insanity through lactation prolonged beyond the ordinary time is more frequent. Again, he is struck with the number of cases admitted with symptoms of dyspepsia and "chronic ill health," and he attributes a considerable number of those to the want of varied and properly cooked meals. As to hereditary transmission of insanity, the Gladesville statistics give only 7·2 per cent., but they are much less complete than the English, owing to the difficulty of getting to know the family history.

We can do no more than briefly indicate some of the other subjects dealt with in this volume; some new double stars, the longitude of Sydney Observatory, the opposition and magnitudes of Uranus and Jupiter, the orbit elements of Comet I. 1880, changes in the surface of Jupiter, catalogue of plants collected by Forrest in North-West Australia, fossil flora of Eastern Australia and Tasmania, piturie, iron acted on by seawater, wood inclosed in basalt, fossils from Palæozoic rocks of New South Wales, schemes of water supply for Sydney, wells in the Liverpool plains.

ON THE APPLICATION OF PHOTOMETRY IN THE STUDY OF THE PHENOMENA OF DIFFUSION IN LIQUIDS

§ 1. SINCE the publication in 1803 of Berthollet's work,[1] in which it is already asserted that the diffusion of salt solutions in water takes place according to the same laws as the propagation of heat in solids, an exact method has frequently been sought for determining the coefficient of diffusion. The attempts in this direction have failed to give concordant results, which may best be judged from a compilation of the numbers expressible in absolute units with reference to chloride of sodium, whose coefficient of diffusion in water has most frequently been measured. The coefficient is stated to be—

By Graham, at 5° C.	88	$\times 10^{-7} \cdot \frac{cm^2}{sec.}$
,, 9° C.	105	
By Fick	116	
By Johannisjanz	53	
By Schuhmeister, at 10° C.	97	

When we inquire into the laws which govern this coefficient we meet with even greater discrepancies. Thus Graham, Fick, and Schuhmeister's researches indicate the increase of the coefficient with the rise of temperature. Johannisjanz finds no such relationship. Thus H. F. Weber, experimenting with sulphate of zinc, concludes that the coefficient of diffusion decreases with increase of concentration. Schuhmeister asserts exactly the contrary.

The importance which diffusion has gained of late as a means of investigating and solving many problems connected with molecular physics[2] induced me to search for a method which should permit me to investigate the processes of diffusion, not alone with more accuracy than heretofore in that direction in which the final results may be ascertained by simple weighing, but also to open up a new field of research which has been inaccessible up to now for want of suitable methods. A detailed description of my method, and a full account of all the circumstances to be observed in carrying out the experiments, will be found in *Wiedemann's Annalen*, vol. xiii. pp. 606–23. I will only give here the general outlines.

In the middle of a large glass trough a glass dish is inverted. On the top of this dish a narrow but thick glass rod is placed horizontally, and upon this four cylindrical vessels of approximately equal height at suitable distances from each other and from the walls of the trough. These are filled with solutions of the salt to be investigated, in such a way that the meniscus attains its maximum height. Water is now poured into the trough till it reaches in height 0·1 cm. below the edge of the shortest cylinder, and the whole allowed to stand for several hours to equalise the temperature. After this, by means of a specially constructed funnel, more water of exactly the same temperature as the water in the trough is introduced, until it reaches a height of several millimetres above the edge of the cylinders.

The apparatus is now left to itself.

To interrupt the experiment a method has been devised, the description of which will also be found in *Wiedemann's Annalen*.

The result is calculated by the formula—

$$D = \frac{l^2 \pi}{4} \left(1 - \frac{c_2}{c_1} \right)^2 \cdot \frac{1}{t},$$

l the depth of the cylinder.

t the time of the experiment.

c_1 the concentration of the salt solution before the experiment.

c_2 the mean concentration of the solution after the experiment.

D the coefficient of diffusion.

§ 2.—Chloride of sodium was the substance experimented with to test the method. Three solutions were prepared, of which the first contained 0·66487, the second 5·8506, and the third 17·695 parts by weight of the anhydrous salt in 100 parts of the solution. The cylinders employed were 2 to 8 cm. in diameter, and 3·45 to 5·036 cm. in depth. The experiments were conducted either in such a way that all the cylinders were filled with the same solution, and the observation made if the cross-cut and the depth of the cylinder had influenced the final result; or else differently concentrated solutions were taken, and the experiment carried out at exactly the same temperature and under the same other conditions. The method was found to be sensitive and accurate. The temperature being 8·5° C., and the duration of the experiment 6·5 hours, the coefficient found was:—

$$\left.\begin{array}{lll}\text{With a solution of } 0{\cdot}66487 \text{ per cent.} & \ldots & 768 \\ \quad ,, \quad ,, \quad 5{\cdot}8506 \quad ,, & \ldots & 808 \\ \quad ,, \quad ,, \quad 17{\cdot}695 \quad ,, & \ldots & 889\end{array}\right\} \times 10^{-8} \frac{\text{cm}^2}{\text{sec.}}$$

The conclusion to be drawn from these numbers is that coefficient of diffusion within the limits of time and concentration indicated decreases according to the law of the straight line as the quantity of salt in solution.

From this result follow:—

1. The numerical value of the coefficient at the same temperature, and the same initial concentration depends upon the duration of the experiment.

2. A fixed state, in which the concentrations in the fluid decrease from bottom to top, according to the law of the straight line, is impossible. Fick's method, which presupposes this state, cannot therefore give correct results.

From the above-mentioned law of the dependence of the coefficient of diffusion on the quantity of salt in solution, and from the first conclusion, it follows that at one and the same tempera ture the value of the coefficient may vary between two widely separated limits. An experiment performed with a saturated solution during the shortest possible time would furnish the one limit, another with a solution containing a quantity of salt approximating to zero would give the other.

The physical cause and the necessity for the mentioned dependence is very simple. If a volume of water be mixed with one volume of concentrated salt-solution, and if a volume of water be mixed with a volume of dilute salt-solution, the resulting contraction in the first instance is greater than in the second. The diffusion of a salt-solution in water has been up to the present considered from a very one-sided point of view. Berthollet and Fick ascribe the diffusion to the forces alone which act between water and salt-solution; modern investigators ascribe it solely to the molecular velocity of the fluid molecules. The experiment shows that the diffusion depends on both, and therefore supports neither of these views entirely. When the cylinder has been filled with concentrated solution the participation of the molecular forces is greater than in the case of weak solution. The numerical value of the coefficient of diffusion, which expresses the result of the experiment, must necessarily be greater in the first case than in the latter. It is therefore in our power to regulate the phenomena of diffusion in a salt solution according to our will; thus when we experiment with concentrated solutions the principal agents at work are the molecular forces, whilst the velocity of the molecules plays the chief part in dilute solutions. The coefficient of diffusion of a salt-solution loses, therefore, entirely the signification of a constant, because in every special case it has another value.

§ 3. The coefficients of diffusion of salt solutions in water at the temperature of 10° C., determined by Graham, Fick, Weber, and Schuhmeister, form a group of numbers which lie between 0·000010 and 0·000002 $\frac{\text{cm}^2}{\text{sec.}}$.

It was of great interest to ascertain the value of the coefficient of diffusion when the quantity of salt is so small that it can neither be estimated with the balance nor with chemical means; when, in short, the solution differs hardly at all from pure water, and when the participation of molecular forces has been brought to a minimum. Such an experiment may be made by tinting water with a salt of great tinctorial power and observing the diffusion of the coloured water into the pure. It is much more difficult to follow these experiments quantitatively, as very small quantities have to be determined. Colorimetrical methods are not sensitive enough.

I therefore tried to measure the concentration photometrically. Nigrosin, which is sufficiently stable towards sunlight, was the colouring matter chosen for the purpose. Hüfner's spectro-photometer was employed. The water was coloured with nigrosin to such an extent that its coefficient of extinction for sodium light amounted to 1·343. The quantity of colouring matter used was so small that the change of specific gravity in the water through its addition could not be ascertained.

A full report of the many difficulties which were encountered and a detailed description of how the experiments were conducted will be found in the above-mentioned *Wiedemann's Annalen*. It was discovered that the coefficient of diffusion was smaller by one decimal place than the smallest known coefficient of a salt.

The method here described urges the investigation of a series of new problems.

In the first place the value of the coefficient must be ascertained for different salts when the salt in solution approximates zero. When these values have been found, only then it will be possible to define in what way the coefficient of diffusion depends on the nature of the salt.

Secondly, it is necessary to find out if it is not possible, by tinting water with different colouring-matters, to obtain a constant, which I propose—analogously to a case already considered by J. Clerk Maxwell—to call *the coefficient of diffusion of a fluid into itself.*

If we suppose a room to be divided into two parts by a movable wall and filled with the same gas at the same pressure and temperature, and we then remove the wall, a diffusion of the gas takes place from the one half of the room to the other, and *vice versâ*, in consequence of molecular velocity. The coefficient of the diffusion which takes place here, Maxwell calls *the coefficient of diffusion of a gas into itself.* It is not measurable, as the molecules of a gas cannot be marked. It can however be calculated from the coefficient of viscosity of this particular gas kinematically measured by multiplying by 1·5435.

When salt-solution diffuses, it is not the salt, but the salt-solution, which diffuses into water. The more dilute the solution, the nearer that state is approached in which pure water diffuses into pure water. How near I have approached this state in my experiments with nigrosin I have no means at present to judge. I have no doubt however that this is the only method of ascertaining the coefficient, which, if once determined in similar manner for every fluid, will be of eminent importance to a kinetic theory of fluids, which has yet to be built up. It is only necessary to bear in mind the assistance rendered to Maxwell by the determination of the coefficients of diffusion of gases by Loschmidt.

S. WROBLEWSKI

THE ROTATIONAL CO-EFFICIENT IN VARIOUS METALS

THE following is an abstract of a Note on the above subject read by Prof. E. H. Hall at the meeting of the British Association at York.

It was discovered two years ago in Johns Hopkins University that when a conductor carrying a current is placed in a magnetic field, the direction of whose force is perpendicular to the current, the current is deflected at right angles to the force and to the original direction of the current. A slip of gold leaf on glass was placed between the poles of Faraday's electro-magnet, with the faces of the gold-leaf perpendicular to the lines of force. Wires were attached one at each end of the strip, for the purpose of transmitting a current through it, and two other wires were led from the middle points of the sides of the strip to a Thomson's galvanometer. When the electro-magnet was not made this galvanometer showed no deflection, but on sending a current through the coil of the electro-magnet a deflection was obtained, and on reversing the direction of this current the deflection was reversed.

Dr. Hopkinson has pointed out that Maxwell, in the first part of his book, treating this subject in the most general way, allows the possibility that something of this kind may take place. Maxwell suggests the name "rotational coefficient"; so the

term which I employ is his, though the fact was not known to him.

I have published an article describing these experiments, which may be known to you, but I have since found some new facts. At Berlin I tested some metals which I had not tried before. I cannot vouch for the quantities within 50 per cent., but I think I can vouch for the direction of the effect. It is not the same for different metals under the same conditions of current and magnetic force. It might have been expected that the effect would be in the same direction in nickel as in iron; but it is not, it is in the opposite direction; nickel acts like gold, cobalt acts like iron. Nickel, silver, gold, platinum, and tin gave an effect opposite to iron.

The most important fact that I have to bring before you is that in zinc the effect is in the same direction as in iron and cobalt.

Table of effects on an arbitrary scale.

Iron	+ 78	Brass	− 1·3
Cobalt	+ 25	Platinum	− 2·4
Zinc	+ 15	Gold	− 6·8
Lead	—	Silver	− 8·6
Tin	+ 0·2	Copper	− 10
		Aluminium ...	− 50
		Magnesium ...	− 50
		Nickel	− 120

The deflection of the current in those marked + is in the same direction in which the conductor itself tends to move in the magnetic field. I cannot vouch for the order of the metals. I have tried three specimens of nickel, and the direction was the same in them all. One of them was pure nickel, furnished me by Prof. Chandler Roberts.

The following remarks were made by the chairman, Sir William Thomson:—

The subject of this communication is by far the greatest discovery that has been made in respect to the electric properties of metals since the times of Faraday—a discovery comparable with the greatest made by Faraday. I look upon it with special interest myself as so closely connected with electrodynamic properties of metals, which formed the subject of my Bakerian Lecture in 1856. I pointed out in that paper, in about § 104, that it was to be expected that magnetic induction would produce change of thermal conductivity and of electric conductivity in different directions in substances perfectly isotropic. I found by mathematical investigation rotational terms, and pointed out that we might expect in bodies which have rotational quality to find the effect of such terms exhibited. But the only influence having that relation to rotation which was necessary for producing the terms in question I pointed out to be the influence of a magnet, and that we might expect that the effect of a magnet upon an isotropic body would be to induce difference of quality in different directions in accordance with the rotatory term, and I said I thought it improbable that the rotatory terms would be found to be null in a body subjected to the influence of a magnet. I look with great delight on Prof. Hall's discovery, as having verified that which I predicted as probable. I did not myself make any serious attempt to discover it. It is the first illustration ever brought out by experiment of one of the most curious and interesting things in the mathematics of æolotropy. The previous mathematical writers dismissed these terms altogether, although they found them in the formula;—dismissed them as something which we could not imagine to exist. I refused to dismiss them, and said there was decided reason that they could exist under the rotational influence which we know to belong to a magnet.

Prof. Rowland said: Mr. Hall had tried the direction of rotation of the plane of polarisation when light is reflected from nickel and iron on Dr. Kerr's plan. The direction was found, if he remembered aright, to be in opposite directions for these two metals. We did not yet know enough to say whether this investigation explains the rotation of the plane of polarisation of light.

Prof. Sylvanus Thompson said he had verified Prof. Hall's result by using a telephone instead of a galvanometer.

Mr. Glazebrook said he had published a paper on the same subject in connection with the rotation of the plane of polarisation of light. Maxwell said this effect (rotation of the plane of polarisation by reflection from a magnet) could be explained by molecular rotation of the particles in the field.

Prof. Fitzgerald asked Sir William Thomson to express an opinion as to how it happens that different substances differ in the direction of this effect. He also remarked that the terms expressing the magnetic force on the matter were the same as those which would express Prof. Hall's observed effect on the current. Was the action to be regarded as an action on the matter or on the current?

Prof. Everett asked whether the current in its deflected condition was oblique (instead of, as usual, normal) to the equipotential surfaces?

Sir William Thomson, in reply, said that effect on matter and effect on the current through it went together, and could not be distinguished. He could not say why the effect in any particular metal was in one direction rather than the other. There was nothing in the mathematical theory to show in which metals it should be in the same direction. Prof. Everett's question might be answered by referring to several corresponding cases. If heat was flowing from end to end of a bar cut obliquely from a crystal, the points of equal temperature in two opposite sides would not in general be exactly opposite to each other. The foundation of the general theory of which this was an illustration had been laid by Prof. Stokes.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—On November 3 Sir William Anson, Bart., D.C.L., Fellow and Sub-Warden, was elected Warden of All Souls' College in succession to Dr. Leighton, deceased. Sir William Anson was Vinerian Reader in English Law.

A Fellowship at University College will be offered for competition about the end of next February. The examination will be in biology and kindred subjects. At the last examination for a Biological Fellowship none of the candidates were judged of sufficient merit, and the election was accordingly deferred.

Candidates for the Brackenbury Natural Science Scholarship at Balliol College must communicate with the Master by letter on or before Friday, November 11. Papers will be set in Chemistry, Mechanics and Physics, and in Biology. There will also be an optional paper in Mathematics, and an essay.

At Christ Church there will be one or more Natural Science Junior Studentships elected next March. Candidates must not have exceeded the age of twenty on January 1, 1882. Papers will be set in Chemistry, Biology, and Physics, but no candidate will be allowed to offer himself in more than two of these subjects.

CAMBRIDGE.—On Monday, November 7, Mr. J. E. Marr, F.G.S., was elected to a Fellowship at St. John's College. In 1878 Mr. Marr obtained a First Class in the Natural Sciences Tripos; in 1879 he received a grant from the University to enable him to travel in Bohemia and study the Cambrian and Silurian rocks there; also in 1880 he went in a similar manner to Norway and Sweden. His paper on the Rocks of Bohemia was published in the *Quarterly Journal* of the Geological Society for November 1880. He is at present lecturing for the University at Barrow, Kendal, and Lancaster.

GLASGOW.—Mr. John Macalister Dodds, B.A., Fellow of St. Peter's College, Cambridge, 4th Wrangler, 1880, has been appointed one of the assistants to Dr. Jack, Professor of Mathematics in the University of Glasgow. Mr. Dodds was a distinguished Glasgow student before proceeding to Cambridge. All the four Professors of Mathematics and Natural Philosophy in the Universities of Edinburgh and Glasgow—Prof. Tait, Prof. Chrystal, Prof. Sir William Thomson, and Prof. Jack—are Peterhouse men.

SCIENTIFIC SERIALS

The American Naturalist for September and October, 1881, contains (No. 9, vol. xv.): Carl F. Gessler, variations in a copepod crustacean (woodcuts).—A. S. Packard, jun., Scolopendrella and its position in nature (places Symphyla as a sub-order of Thysanura).—W. H. Dall, American work in the department of recent mollusca in 1880.—D. G. Brinton, notes on the Codex Troano and Maya chronology.

No. 10, vol. xv.: D. H. Campbell, on the development of the stomata of Tradescantia and Indian corn (woodcuts).—Cyrus Thomas, the age of the manuscript Troano.—J. Walter Fewkes, the Physophoridæ (iii.).—R. E. Cull, the Loess in Central Iowa.—A. S. Packard, jun., on the early stages of the

fiddler crab and of Alpheus.—Hartley Barnes, Reason: a psychological distinction.

Bulletin de l'Académie Royale des Sciences de Belgique, No. 8.—Palæontological documents relating to the Cambrian formation of Ardenne, by M. Malaise.—Magic square of the Villa Albani (Rome), by M. Catalan.—On the specific weight of sulphur of Ch. Saint-Claire Deville, by M. Spring.—On the dilatation of sulphur, selenium, and tellurium, by the same.—On the rotatory power of albumen of a dog's blood, by M. Fredericq.—Latitude on a voyage; graphic process, by M. Adan.—On the monazite of the quarries of Nil, St. Vincent, by M. Renard.—Description of a new and precise registering barometer, by M. Delaey.

Journal de Physique, October.—Determination of the wave-lengths of the very refrangible radiations of magnesium, cadmium, zinc, and aluminium, by M. Cornu.—Researches on the refringent power of liquids (continued), by M. Damien.—Experimental researches on the capacity of voltaic polarisation (concluded), by M. Blondlot.—Measurement of the energy expended by an electric apparatus, by M. Potier.—Experiment in optics, by M. Dubois.

La Natura, October.—On the thermal radiation and the temperature of the sun, by S. Cattaneo.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti, vol. xiv. fasc. xv.—Discussion of some mistakes regarding American vines, by Count Trevisan.—Alteration of muscular fibres in a case of locomotor ataxy, by Prof. Golgi.—On photo-anæsthesia in insane persons, by Dr. Raggi.—On variations in the velocity of the arterial current following paralysis of the vagus nerve, by Prof. Solera.—Anomaly in a parrot (*Psittacus Amazonicus*, Lin.), by Prof. Maggi.—Elimination of nitrogen from tyrosine, by Prof. Korner and Dr. Menozzi.—On some products of transformation of chinoline, by Prof. Korner.

Rivista Scientifico-Industriale, September 30.—The axis of rotation of Mercury, by T. Zona.—A compressed air bell-rheometer, by S. Scardona.

Rendiconti delle Sessioni dell' Accademia delle Scienze dell' Istituto di Bologna, 1880–81.—We note here the following:—On the internal discharges of condensers, by E. Villari.—Adaptation of species to their environment; new observations on the genetic history of Trematodes, by G. Ercolani.—On the mode of termination of nerve-fibres in the cornea, and the internal construction of the axis-cylinder, by G. V. Ciaccio.—Anthropometric researches on the Bolognese, by G. Peli.—Chemico-toxicological researches on a putrefied brain, by C. Stroppa and G. Tomani.—Morphological, anatomical, and organic researches on the various species of the genus Citrus, by G. Cugini.—On the course of the river Po, and on works which must be undertaken in presence of danger which threatens the neighbouring population, by P. Predieri.—New method of obtaining pure gastric juice and determining its physiological properties, by L. Vella.—Electric shadows, by A. Righi.—On defective births in the females of *Myoxus glis*, and in the human species, by G. B. Ercolani.—On the ovulation of *Distoma hepaticum* and *lanceolatum* in sheep and oxen, by G. B. Ercolani.

SOCIETIES AND ACADEMIES

London

Chemical Society, November 3.—Dr. Gilbert in the chair.—The following papers were read:—On citraconic and mesaconic ethers and malic and fumaric acids, by W. H. Perkin. The author has carefully investigated the physical properties of the methylic and ethylic ethers of citra- and mesaconic acids. Dr. Gladstone has also measured their refractive indices. The citraconic ethers boil at a higher temperature than the mesaconic ethers, but their specific gravities, magnetic rotatory power, and refractive indices are lower. Only one anhydride can be obtained from maleic and fumaric acids, one from citra- and mesaconic acids, and one from α and β coumaric acids. Maleic anhydride can be obtained directly from malic acid by heating with an excess of acetylic chloride.—On the action of potassium cyanide on bismuthous nitrate, by M. M. P. Muir. A puce-coloured body is formed, $Bi_5(CN)_6O_{15}$; by heating with strong potash Bi_4O_7 is obtained.—On the atomic weight of bismuth, by M. M. P. Muir. The author has analysed bismuthous chloride, and obtained as a mean atmospheric weight 210·46, but he is not satisfied with the results, and hopes to obtain better numbers by the synthesis of bismuthous iodide.—Additional observations on the halogen salts of bismuth, by M. M. P. Muir.—Note on the action of sulphuric acid on zinc and tin, by M. M. P. Muir and C. E. Robbs.—On the volumetric estimation of bismuth in the form of oxalate, by M. M. P. Muir and C. E. Robbs.—Note on the influence of water on the reaction between potassium iodide and chlorine, by M. M. P. Muir and R. Threlfall.—Laboratory notes, by M. M. P. Muir. 1. Lecture experiment showing the effect of "*a*" time, "*b*" temperature, "*c*" mass. This consists in adding a solution of bismuth iodide in hydriodic acid to each of three beakers, one containing 100 cc. of cold water, 100 cc. of hot water, and 500 cc. of cold water. 2. The solution of manganese dioxide and manganese ores in hydrochloric acid is much hastened by potassium iodide. 3. A new method of detecting tin in the presence of antimony: by boiling with metallic copper and testing for stannous salt with mercuric chloride. 4. To detect the haloid acids in presence of nitrous and nitric acids.—On suberone, by R. S. Dale and C. Schorlemmer.—On sulphonic acids derived from isodinaphthyl, by Watson Smith and T. Takamatsu.—On phenyl naphthalene, by Watson Smith and T. Takamatsu.—On dimethylmalonic acid and dimethylbarbituric acid, by L. T. Thorne. The author confirms the conclusions arrived at by Conrad and Guthzeit.

Paris

Academy of Sciences, October 31.—M. Wurtz in the chair.—On account of the death of M. Bouillaud the *séance* was adjourned.—*Comptes rendus* for the week contains—Observations of Cruls' comet (*b* 1881) at Marseilles Observatory, by M. Stephan.—Elliptic elements of the same comet, by M. Bossert.—Observations of comets *c* 1881 (Schaeberle), *d* 1881 (Encke), *e* 1881 (Barnard), *f* 1881 (Denning), at Paris Observatory, by M. Bigourdan.

Vienna

Imperial Academy of Sciences, October 20.—V. Burg in the chair.—L. F. Tiefenbacher, on the forest and its relations to landslips (a supplement to a work by the same author, on landslips, their causes, effects, and treatment).—F. Austerlitz, a contribution to the ballistic problem.—E. Mahler, theory of curvature of an *n*-fold manifoldness.—E. Weiss, computation of the elements and ephemeris of Barnard's comet (continued).

Göttingen

Royal Society of Sciences, June 4.—Absolute measurement of the strength of terrestrial magnetism by a galvanic method without determination of time, by F. Kohlrausch.—Theory of curves of double curvature, by A. Enneper.—Remarks on some transformations of surfaces, by the same.

August 6.—Lycopodin, by K. Bædeker.

SYSTEMATIC MINERALOGY

Text-Book of Systematic Mineralogy. By Hilary Bauerman, F.G.S., Associate of the Royal School of Mines. (London: Longmans, Green, and Co., 1881.)

THE text-books of Mineralogy written for English readers are so extremely small in number that the publication of a new one may be almost looked upon as an epoch in the history of the science. The text-books already in existence are in many respects very unsatisfactory, and in general character fall far below the standard of those of France and Germany. The symbols adopted in them for the faces of crystals are generally those of Naumann, whilst the simple and elegant symbols of Miller, if mentioned at all, seem to be regarded as intended for ornament rather than for use. As for the advances made by theoretic crystallography during the last quarter of a century, no account, save that to be found in the excellent little work of Mr. Gurney, has yet been offered to the English student.

Mr. Bauerman had thus a clear field and a splendid opportunity. It will be interesting to consider how far the result of his labour is worthy of the occasion.

We find, on opening the book, that the Descriptive Mineralogy, which the author's wide experience and extensive travel should render highly instructive, has been assigned through force of circumstances to a supplementary volume: of the 367 pages of the present one, 200 are given up to the geometrical, 100 to the physical, chiefly optical, and the remainder to the chemical and other properties of minerals. One immediately remarks with pleasure the numerous figures of crystals distributed throughout the work, all well drawn and clearly printed, and what is almost as important to the student, having wherever practicable the Millerian indices affixed to the faces.

On coming to the letterpress, however, one soon finds that there is something wrong; in fact, from the first page almost to the last there seems an evident disposition to perplex the reader. The style is very confusing throughout. On p. 5, for instance, we are informed that "quartzite and statuary marbles are aggregates of particles of quartz and calcite into masses of a slaty or granular texture." On p. 7 we find the following:—

"The leading property of crystals, as distinguished from mere geometrical solids, is the invariability of the angles between corresponding faces in different individuals of the same substance. There is usually a very marked *symmetry* to be noticed in the arrangement of their plane faces and edges, and occasionally of their points also, although the latter symmetry is not essential, crystallographic symmetry being one of direction and not of position, so that two parallel planes or two parallel lines are not distinguished from one another, and on that account the invariability of the angles is a paramount consideration."

Leaving out of sight the fact that the accuracy of the above distinction may be very reasonably contested, we much doubt the ability of the ordinary mineralogical student to master the compound nature of the latter sentence. On p. 10 we are puzzled on being told that "a polyhedron may be turned through an aliquot part of a whole revolution without its position in space as a whole being changed"; on p. 12 we find that the tetragonal system is characterised by the existence of *two* axes of binary symmetry, while on p. 112 *four* are mentioned; on p. 15 we are informed that if α, β, γ are all different, the molecular net-work has no symmetry, while on the following page it is said that, granted certain relations between these different quantities, there will be symmetry; on p. 19 we are told that the values of h, k, l are in no wise altered by multiplying them by any numerical co-efficient; and from p. 24 it will be concluded that a crystal with a "concave" angle is necessarily a twin.

On p. 36 it is stated that "the test of whether we have really four faces of *one* crystal is the rationality of this anharmonic sine-ratio when reduced to numbers" It is a well-known fact that in every zone of the cubic system, and in particular zones of the tetragonal and rhombohedral systems, the anharmonic ratio of any four planes belonging to *two* twinned crystals will be rational.

The account of the inter-relations of the various holohedral forms of each crystallographic system is not such as will relieve this branch of the subject from being still looked upon by the English student as somewhat dry and wearisome, while the attempt to evolve the hemihedral forms must cause the learner to despair. Thus the chapter on the Tetragonal System begins as follows:—

"The complete symmetry of this system is contained in an upright prism upon a square base, which has quaternary symmetry about a principal axis parallel to the vertical edges, and binary about four lateral axes."

Instead of an explanation there is then a statement of the fact that only certain permutations of the indices are possible: next follows a calculation, one of the principal features of which is the use of some spherical triangle characterised only by the fact that it is described *about* the pole of the principal axis and has a side represented by π, which symbol has been unfortunately selected to represent an *arbitrary* arc. The hemihedral forms are then arrived at by arranging the symbols of the faces of a complete form in a particular order, and then halving the faces, or the symbols, or the table, it is not clear which, in some symmetrical way not easy to discover (see pp. 89 and 120).

On p. 152 we find that, in the case of oblique crystals the axis of symmetry is a direction of "physical equivalence," while from p. 156 we should conclude that a face is "crystallographically possible" when it has a similar face parallel to itself.

In the discussion of twin crystals the relation in which the twin axis and the twin plane stand to the lines and planes of the crystalloid system is not clearly expressed. It may be worth while to point out that on p. 170 the somewhat common error is made of considering a face of the cube as the twin plane of the two interpenetrant tetrahedra, whereas a little reflection will make it clear that the twin plane is really a dodecahedral face. On p. 352 the striations on the cube faces of iron pyrites are, strange to say, referred to as *twin striations.* In describing a goniometer, of which the picture on p. 192 is no doubt very ideal, it is remarked that "the angle through which the circle is rotated will be the supplement of the dihedral angle required, *if it was originally set to zero.*"

On the same page a probable injustice is done to the instrument, for we find that "in all cases the observation must be often repeated to obtain results of any value." What can be meant by the statement on p. 198, that the octahedron, or unit pyramid, is always the largest, and the cube rectangular prism, or pinakoid the smallest, of the constituent forms of any combination? On p. 205 we learn that density and hardness are common to all solids alike, and are therefore *independent of structure*. A definition (p. 212) informs us that a substance is *ductile* when it can be cut with a knife, but crushes to powder under a hammer, copper pyrites being cited as an example; and on the same page we find as an illustration of toughness of a mineral that "Malleable native Copper, especially when intimately mixed with siliceous vein-stuff and some varieties of Hematite and Iron Pyrites, has the property of toughness in a high degree."

The discussion of the optical properties is more unsatisfactory still. On p. 225 is to be found the following remarkable statement:—

"The movements in such a medium can only be reduced to order by supposing them to be made up of portions of homogeneous substances of different properties, and treating each one separately."

The proof of the existence of a minimum angle of deviation as submitted on p. 233 can scarcely be meant as serious; but to this curious proof should not have been appended an erroneous translation of the formula into words. On p. 235 the azimuths of vibration of an ordinary ray of light are said to change *continuously*, but so very rapidly that the changes are not perceptible to the eye; on the following page we read of "impulses having different velocities." Perhaps matters reach a climax about p. 245, where the intelligibility of the book for a brief period suffers total eclipse, as perhaps may be imagined when we read that "these orthogonal *forces* are called the *axes* of optical elasticity." On p. 263 one of the rays produced by double refraction is said to be "an extraordinary ray in all directions but those of the optic axes." Phosphorescence is, according to p. 290, "the power of emitting light in a dark place." On p. 293 we find a serious misapprehension as to the precise nature of the method employed by Fizeau for the determination of the expansion of crystals. One infers from the explanation here given that the interference rings, produced by help of a plane crystal surface and a lens, are *distorted* on change of temperature, and that the measurement of this distortion serves for the determination of the coefficient of dilatation for different directions in the plane surface; as a matter of fact Fizeau by his method determined with each crystal section the dilatation in only *one* direction, namely, that normal to the plane surface.

It is difficult to understand how Mr. Bauerman has contrived to allow so many loose statements to creep into his book; and we can only surmise that he has himself not had the time or the opportunity for a careful revision of the proofs. At any rate it will be evident from the above that a careful revision is absolutely required before the book can take its proper place in mineralogical literature. We trust that the present edition may be speedily disposed of, and that Mr. Bauerman will thus be enabled to offer to the English student a second and revised edition of a work, the want of which is urgently felt by every teacher of the subject.

L. FLETCHER

A TREATISE ON CHEMISTRY

A Treatise on Chemistry. By H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., Professors of Chemistry in the Victoria University, Owens College, Manchester. Vol. III. The Chemistry of the Hydrocarbons and their Derivatives, or Organic Chemistry. Part I. 8vo. (London: Macmillan and Co., 1881.)

THE term "Organic Chemistry" was originally used to denote the chemistry of compounds produced in the living vegetable or animal organism, all of which contain the element CARBON. For a long time indeed it was supposed that these compounds were peculiarly the products of living organisms, being formed under the influence of a so-called *vital force*, and that they could not be produced, like those of the mineral world, by artificial means. But the course of research has shown that this idea was erroneous, and that a large number of the more important organic bodies—hydrocarbons, alcohols, acids, &c., originally known only as products of the living organism—can be formed synthetically from their ultimate elements. The name "Organic Chemistry" has thus acquired a new signification, and in its widest sense is now used to denote the chemistry of carbon-compounds. As however some of these compounds, viz. the oxides and sulphide of carbon, have long been known to be producible by direct combination of their elements, and have accordingly been described in Manuals of Chemistry amongst inorganic compounds, the authors of the present treatise have thought it desirable to use the term "Organic Chemistry" in a somewhat narrower sense, viz. as signifying the CHEMISTRY OF THE HYDROCARBONS AND THEIR DERIVATIVES.

The volume commences with a historical sketch of the development of this department of the science, tracing it from the few facts respecting organic bodies known to the ancients, to the discoveries of Scheele, Lavoisier, Berzelius, Liebig, and numerous other workers, down to the present time—dwelling especially on the idea of Compound Radicals introduced by Lavoisier, and further developed by Berzelius, and by Liebig and Wöhler in their classical research on Bitter Almond Oil and its Derivatives, published in 1837—thence to the theories of Substitution and Types, founded chiefly on the researches of Dumas, and of Laurent and Gerhardt, and to the subsequent fusion of the Radical and Type theories brought about by the experiments of Williamson on Etherification, and those of Wurtz and Hofmann on the Compound Ammonias.

The next division of the work treats of the methods of ORGANIC ANALYSIS, which are explained in considerable detail, and illustrated by admirable diagrams; also of the determination of Vapour-density, in which the latest methods introduced by Victor Meyer are fully described, after which we come to the Determination of Molecular Formulæ, the explanations of which are characterised by singular clearness.

Next follows the CLASSIFICATION OF CARBON-COMPOUNDS, which are divided into groups according to the mode of linking of the carbon-atoms, the principal divisions being the Fatty or Paraffin group, in which the carbon-atoms are joined together in a single open chain, and of the Aromatic or Benzene group, in which the

atoms are supposed to form closed chains. Objections have sometimes been raised against this division as somewhat arbitrary; but we cannot help thinking that it is justified by the peculiar kind of isomerism, depending on the relative position or "orientation" of the substituted groups or radicals which exists amongst benzene derivatives.

The formation, constitution, and general properties of the Paraffins are next explained, together with those of the several groups of bodies, Alcohols, Acids, Amines, &c., derived from them by substitution, and the remainder of the volume is devoted to the special description of these several compounds, which are arranged according to the number of carbon-atoms contained in them, beginning with the lowest or Methyl-group, the fundamental hydrocarbon or paraffin of each group being first described, and then in succession the Alcohols, Ethers, Nitrogen-bases, Phosphorus-bases, Organo-metallic compounds, Aldehydes, Acids, Ketones, Sulphur-compounds, &c., derived from it.

All these compounds are clearly and ably discussed, especial attention being given to those which are of industrial importance, *e.g.* common Alcohol, Acetic Acid, and the Higher Acids of the Fatty series, which enter into the composition of soap. Several industrial processes are described in considerable detail, and amply illustrated by figures, *e.g.* the separation of the Paraffin-oils by fractional distillation, the manufacture and rectification of Alcohol, the testing of the strength of Spirits and of Wine and Beer, the preparation of Vinegar, and the manufacture of Soap. And here perhaps it may not be out of place to point out the great practical importance of Organic Chemistry, which, strange to say, has been called in question by some writers in the periodical press, who have spoken of it as consisting, in great part, of elaborate trifling about compounds of little practical importance, but rejoicing in names of fearful length, and formulæ of excruciating complexity—and in fact treating this branch of chemical science as altogether of second-rate importance in comparison with Mineral Chemistry. Now the importance of this last-mentioned branch of chemistry, which includes the description of the Metals and their Compounds, is of course beyond all question; but it is perhaps not too much to say that at least an equal value in a practical point of view may be ascribed to that department of the science which is concerned with the materials of our food and clothing, and with the constitution of the compounds which make up the bodies of plants and animals. To remove any doubt that may yet exist as to the practical importance of Organic Chemistry, we can imagine nothing more effectual than a perusal of the volume under consideration, the appearance of which will doubtless be hailed with pleasure by all who are interested in the subjects of which it treats. H. WATTS

OUR BOOK SHELF

Acoustics, Light, and Heat. By Thomas W. Piper. (London: George Philip and Son, 1881.)

THIS little work is not without its merits, the descriptions of the simpler phenomena and laws of these branches of physics being for the most part clear, accurate, and couched in easy language. The arrangement adopted in the chapters of the book is a departure, and we think not a very wise one, from the usual order of subjects in elementary text-books of physics. After a preliminary chapter on the atmosphere, its elasticity and its weight, the author plunges into vibratory motion, and under this head treats of acoustics. Chapter III. is on rectilinear motion, under which heading we have the following subjects:—The reflection of sound, the linear propagation of light, reflection of light and its applications, convection, radiation, and conduction of heat, laws of curved mirrors, laws of refraction, lenses, magic lantern, refraction of sound, spherical aberration of lenses, and, lastly, properties of matter. We have quoted these in the order in which they occur, and cannot help thinking that, however clearly the individual subjects are treated of, this heterogeneous lumping together of them must hamper the comprehension of beginners. Chapter IV. deals with the conservation of matter, including expansion by heat; Chapter V. is on thermometers. Chapter VI., on the conservation of energy, is another example of the author's peculiar method. It begins with the correlation of forces, deals with the prismatic spectrum, diathermancy, acoustic resonance, the laws of vibrations of strings, and specific heat. The book concludes with a chapter on sensation, optical and acoustical. Except for these aberrations of arrangement, and for one or two slips, the book would be a satisfactory one for beginners in natural philosophy.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Parasitic Habits of Molothrus

IN the "Origin of Species" I adopted the view maintained by some writers, that the cuckoo lays her eggs in other birds' nests, owing to her habit of laying them at intervals of two or three days; for it could hardly fail to be disadvantageous to her, more especially as she has to migrate at a very early period, to have young birds of different ages and eggs all together in the same nest. Nevertheless this occurs with the non-parasitic North American cuckoo. If it had not been for this latter case, it might have been argued that the habit of the common cuckoo to lay her eggs at much longer intervals of time than do most other birds, was an adaptation to give her time to search for foster-parents. The Rhea or South American ostrich is believed likewise to lay her eggs at intervals of two or three days, and several hens deposit their eggs in the same nest on which the male sits; so that one hen may almost be said to be parasitic on another hen. These facts formerly made me very curious to learn how the several species of Molothrus, which are parasitic on other birds in very varying degrees, laid their eggs; and I have just received a letter from Mr. W. Nation, dated Lima, September 22, 1881, giving me information on this head. He says that he has there kept in confinement for a long time *Molothrus perpurascens*, and has likewise observed its habits in a state of nature. It is a resident species of Western Peru, and lays its eggs exclusively in the nests of a sparrow (*Zonotrichia*), starling (*Sturnella bellicosa*), and a pipit (*Ænthus chii*). He then proceeds: "The eggs of the sparrow are very much like those of the Molothrus in size and colour. The eggs of the starling are larger and somewhat different in colour; while the eggs of the pipit are very different both in size and colour. Generally one egg of the Molothrus is found in a nest, but I have found as many as six. The young Molothrus does not always eject its foster-brothers; for I have seen a young one nearly fully feathered in a nest with two young

starlings. I have also found two young birds of the Molothrus nearly fully feathered in the nest of a starling; but in this instance the young starlings had been ejected from the nest." He then states that he had long kept in confinement a male and female of this species of Molothrus, which are now six years old. The hen began to lay at the age of two years, and has laid each time six eggs, which is the number laid by Icterus, a near ally of Molothrus The dates on which the eggs were laid this year are as follows:—February 1, 6, 11, 16, 21, and 26; so that there was an interval of exactly four clear days between the laying of each egg. Later in the season she laid six additional eggs, but at much longer intervals and irregularly, viz. on March 8, April 6 and 13, May 1, 16, and 21. These interesting facts, observed by Mr. Nation in relation to a bird so widely distinct from the cuckoo as is the Molothrus, strongly support the conclusion that there is some close connection between parasitism and the laying of eggs at considerable intervals of time. Mr. Nation adds that in the genus Molothrus, out of every three young birds he has invariably found two to be males; whereas with Sturnella, which lays only three eggs, two of the young birds are, without any exception, females.

CHARLES DARWIN

Down, Beckenham, Kent, November 7

The Velocity of Light

IN reply to Mr. Macaulay (NATURE, vol. xxiv. p. 556) I will endeavour to explain more clearly the statements, made in my former communication on this subject (NATURE, vol. xxiv. p. 382). On one important point the explanation will include a correction.

With reference to the group-velocity U, we know from Fourier's theorem that any disturbance travelling in one dimension, can be regarded as resulting from the superposition of infinite trains of waves of the harmonic type, and of various amplitudes and wave-lengths. And we know that any one of these trains, of wave-length λ, is propagated unchanged with a velocity V, which we regard as a known function of λ, dependent upon the nature of the medium.

Unless we can deal with phases, a simple train of waves presents no mark by which its parts can be identified. The introduction of such a mark necessarily involves a departure from the original simplicity of a single train, and we have to consider how in accordance with Fourier's theorem the new state of things is to be represented. The only case in which we can expect a simple result is when the mark is of such a character that it leaves a considerable number of consecutive waves still sensibly of the given harmonic type, though the wave-length and amplitude may vary within moderate limits at points whose distance amounts to a very large multiple of λ. We will therefore suppose that the complete expression by Fourier's series involves only wave-lengths which differ but little from one another, and accordingly write it—

$$a_1 \cos\{(n+\delta n_1)t-(\kappa+\delta\kappa_1)x+\epsilon_1\}$$
$$+\, a_2 \cos\{(n+\delta n_2)t-(\kappa+\delta\kappa_2)x+\epsilon_2\}+\ \ldots\ ,$$

or in the equivalent form—

$$\cos(nt-\kappa x)\,\Sigma a_1 \cos(\delta n_1 t-\delta\kappa_1 x+\epsilon_1)$$
$$-\sin(nt-\kappa n)\,\Sigma a_1 \sin(\delta n_1 t-\delta\kappa_1 x+\epsilon_1),$$

where $\kappa=2\pi/\lambda$, and $n=\kappa V$. From this we see that, as in accordance with the suppositions already made,

$$\frac{\delta n_1}{\delta\kappa_1}=\frac{\delta n_2}{\delta\kappa_2}=\ \ldots\ =\frac{dn}{d\kappa},$$

the deviations from the simple harmonic type travel with velocity $dn/d\kappa$, and not with velocity n/κ, that is with velocity $d(\kappa V)/d\kappa$, and not with velocity V.

I now pass on to the theory of Foucault's experiment. If D be the distance between the fixed and moving mirrors, ω the angular velocity of the latter, then the angle through which the mirror turns in the time occupied by the wave in making the double journey is $2D\omega/V$, and the angular deflection θ, which is the immediate subject of observation, is according to the usual view—

$$\theta=\frac{4D\omega}{V}.$$

Now it is here assumed that the deflection is due merely to the change of position of the mirror between the two reflections, and that the wave returns to the mirror with its front parallel to the position occupied immediately after the first reflection, as would be the case if the mirror were at rest. But if V be a function of λ, this assumption is not true. Besides the deflection above considered, there is another depending upon the fact that the wave front rotates in the air between the two reflections. The rotation is a consequence of the inclination to one another of successive wave fronts, which involves a variation of wave-length and therefore of velocity at points situated on the same wave-front in a line perpendicular to the axis of rotation. Denoting distances measured along this line by x, we have for the angular velocity of the wave's rotation—

$$\omega'=\frac{dV}{dx}=\frac{dV}{d\lambda}\,\frac{d\lambda}{dx},$$

in which $d\lambda/dx$, representing the angle between successive wave-fronts of similar phase, is equal to $2\omega\lambda/V$. Accordingly—

$$\omega'=2\omega\frac{d\log V}{d\log\lambda},$$

and the actually observed rotation is—

$$\theta=\frac{4D\omega}{V}\left(1-\frac{d\log V}{d\log\lambda}\right).$$

The result of a calculation which leaves the aërial rotation out of account is therefore not V, but—

$$\frac{V}{1-\dfrac{d\log V}{d\log\lambda}}$$

Now

$$U=\frac{d(\kappa V)}{d\kappa}=V\left(1+\frac{d\log V}{d\log\kappa}\right)=V\left(1-\frac{d\log V}{d\log\lambda}\right);$$

so that the result of the experiment is V^2/U, and not as previously stated the group velocity U itself. The error arose from a mistake as to the direction of the effect of ω'.

The force of the arguments which I founded upon these considerations is increased rather than diminished by the correction, and with Mr. Michelson's evidence on the same side of the question almost excludes any appreciable variation of V. It should be noticed that by the combination of the two methods of the toothed wheel and of the revolving mirror we have the means of determining both V and U, and the results of Cornu and Michelson appear to prove, independently of astronomical observation, that there is no sensible difference between them.

Indeed by a slightly varied arrangement it would seem possible to determine V directly from Foucault's experiment. If a convex lens were so interposed at the distant station that the fixed mirror occupied its focus, the sides of short and long wave-length would be interchanged, and thus the rotation acquired during the outward journey would be neutralised during the return.

RAYLEIGH

The Struggle of Parts in the Organism

I AM very glad to learn that Mr. Romanes fully accepts as "well-known and unquestionable" the definition of the term *law of nature* which I propounded as expressing its true scientific sense; but I would suggest to him, as to other writers who are accustomed to speak of such laws as "governing" phenomena,[1] whether the use of such "metaphorical" language is not objectionable, as tending to keep up in the *un*scientific mind the notion of the "coercive" and "self-sufficient" agency of natural laws. I am glad also to be able to express my entire accordance with Mr. Romanes in regard to the inferiority of the teleological argument based on *special instances* of adaptation of means to ends, to that which is based on the *general order* which we designate by the term law. For I maintained this view even in that remote pre Darwinian age in which my scientific life commenced, urging to the best of my young ability, forty-three years ago,[2] that the principles admirably laid down by Whewell in regard to physical inquiry, viz. that final causes should be excluded, because "we are not to assume that we know the objects of the Creator's design, and put the assumed purpose in the place of a physical cause," and that "the notion of design and end is transferred by the researches of science from the

[1] I continually meet with this phrase in the pages of NATURE.

[2] See *British and Foreign Medical Review* for April, 1838: "Physiology an Inductive Science."

region of facts to that of laws," are no less applicable to physiology than to physics; although Whewell himself (in his "History of the Inductive Sciences") had maintained the contrary. The full acceptance of the doctrine of evolution as our highest expression of the *order* of creation seems to me to lead to a much nobler conception of the Intelligent Cause of that order than any accumulation of such individual adaptations as might be made by the "mechanic-god" of Paley.

WILLIAM B. CARPENTER

56, Regent's Park Road, N.W., November 14

The Aurora and its Spectrum

YOU have already illustrated in NATURE the aurora and electric storm of January 31. Though somewhat tardily, another drawing with a description of this fine display has found its way into my hands, of sufficient interest, I think, to be added to those already published. It comes from Mr. C. L. Prince, the well-known meteorologist of Crowborough Beacon, Tunbridge Wells, who says, "I inclose a photo of my sketch on a slate.[1] I had a splendid sight of the aurora at about 9h. 15m. It soon became very hazy, but I saw it again at 11h. 15m., when I made the sketch (see drawing). The arch was exceedingly well defined, and extended about 80° along the horizon. At 11h. 20m. some more brilliant streamers shot up along the whole convexity of the arch, and the two *patches* of *light* became very tremulous, almost shifting a little from right to left; but I particularly noticed that they did not vibrate *simultaneously*, *i.e.* if one indicated motion the other was quiescent *until* the first had ceased to show excitement, and this action was alternating for nearly an hour. At 11h. 40m. the arch had much contracted, and by midnight had nearly faded away. The whole phenomenon was

free from colour. I noticed a few small meteors. The night was quite calm; wind south-west."

This account seems to me interesting in connection with an observation made by my friend Dr. Vogel of Potsdam, that during the aurora of April 9, 1871, certain lines in the spectrum alternated in intensity with the character of the discharge, some brightening as others faded.

Mr. Prince does not mention any spectroscopic observations, and while noting this will you permit me to make a few remarks on the "spectrum of the aurora," an old hobby of mine. I notice that Dr. Spottiswoode, P.R.S., in his lecture delivered before the British Association at York on September 5 last (NATURE, vol. xxiv. pp. 572, 3, "On the Electric Discharge, its Forms and Functions,") has referred to the aurora in connection with experiments showing that the discharge in rarefied gases differs from that at higher pressures, and that the difference corresponds to that observed between the flickering play of the aurora and the crashing spark of the lightning-flash. After then referring to the questions of height and colour of the auroral discharge, Prof. Stokes' theoretic view of the connection of earth-currents, disturbances of the magnetic needle, and solar radiation is dwelt upon. In NATURE, vol. xxiv. pp. 613-18 (lecture by Prof. Stokes, Sec.R.S., in the South Kensington Theatre, on "Solar Physics"), this theoretic view is set forth, and the aurora is described as a flash of lightning passing through the higher regions of the atmosphere where the air is rarefied. There are, I think, some objections to this theory founded upon certain circumstances of the aurora itself, such, for instance, as the well-authenticated cases of auroræ seen close upon the surface of the earth.

The passage, however, in Prof. Stokes' lecture which particularly struck me is this: "But what of the auroræ? It has long been recognised that the aurora is an electrical phenomenon. It has been supposed to be imitated, *and there can be no doubt that the supposition is a correct one* [the italics are mine] by sending an ordinary electric discharge through a highly exhausted tube."

Now it may be true that the aurora is thus imitated so far as external appearance is concerned, and it has long been a favourite idea that this imitation in some way extended to the aurora's actual composition; but what does that Ithuriel spear, the spectroscope, say upon that point—a point which gains the more importance from the fact that such an instrument is mentioned by Prof. Stokes (p. 614) as the true touchstone for the aurora? It says positively that Prof. Piazzi Smyth's citron line, the one true test of the aurora, has never yet been seen in any electric discharge whatever which we have yet produced, whether in air at ordinary pressure, or rarefied; that the red line (its companion in some auroræ) is equally noticeable for its absence therefrom; and that of the remaining faint and less marked lines one or two only have with doubt and uncertainty been by some referred to the air spectrum as excited by the electric spark or glow. The late Prof. Ångström endeavoured to place some of these fainter lines in accord with the spectrum bands of the violet pole in Geissler air-tubes, but the comparison failed on critical examination. Prof. Vogel has also considered the aurora might probably be an air-spectrum modified by conditions of temperature and pressure. The Professor's actual line comparisons, however, quite failed as to the citron and red lines, and could hardly be called a success as to the fainter ones. In fact any analogy between the aurora spectrum and the spectrum of the electric discharge in air is all but hypothetical, and the aurora still maintains that mysterious quality which distinguishes it from electric discharges of all sorts, and indeed everything else, viz. its peculiar spectrum.

I therefore again plead the necessity for spectrum observations in connection with the aurora, a point from which Prof. Stokes' lecture, I am afraid, owing to its absence of any remarks on the subject (save that before referred to) is somewhat calculated to draw them away. It is certainly *possible* that some special gas *may* exist in the upper regions of the atmosphere giving rise to the citron, perhaps the red, lines; but then (as Prof. Smyth remarks) if so, why, being an emission spectrum in the aurora, does it not, according to the theory of exchanges, appear as an absorption spectrum or dark lines in the solar spectrum? Even, too, could this be shown, it would still remain an unexplained fact that such a gas has hitherto failed to be recognised in any other body, celestial or terrestial.

To sum the matter up, the electric discharges in vacuum-tubes, as tested by Prof. Stokes' prism and slit, no more represent the aurora than did the cirrus cloud illuminated by the light of the moon, mentioned by him, which also simulated it.

Upon reliable authority the spectrum of lightning may be considered that ordinarily given by a spark in air; but when we come to rarefied discharges and the aurora, the same comparison does not hold good; and where the electrician has to leave the matter, the spectroscopist has yet to take it up.

To aid in solving the aurora's mystery I would invite all spectroscopists, armed with suitable instruments, persistently to aim at accurate micrometer readings of the aurora spectrum. The approximate places of the lines are pretty well established, but their actual wave-length positions are much wanted, for so only may we hope to master one of the remaining riddles of science.

J. RAND CAPRON

Guildown, November 1

[1] I commend this method of sketching to other observers, the slate pencil showing white on the dark slate being readily photographed with good effect, displaying the aurora light on a dark ground.—J. R. C.

Arctic Research

"PROGRESS of Arctic Research since the Foundation of the British Association," by C. R. Markham, C.B., F.R.S. Such is the title of a very able and instructive paper read before the Geographical Section of the British Association at York on September 6 last, and published *in extenso* in the November number of the *Proceedings* of the Royal Geographical Society. The casual reader of this history may suppose it to be a fair and correct record of half a century of Arctic exploration, and that

the names of distinguished men commanding naval expeditions, who themselves, or the officers under them, did a large amount of discovery and good scientific work, are mentioned, however briefly. Yet this is far from being the case. True, some of those expeditions which have been considered unworthy of notice were sent to the far north to gain tidings of the lost expedition under the good and noble but unfortunate Franklin; yet, in addition to doing an immense extent of sledging, by which many hundred miles of *new* coast were traced, they collected much scientific information, little, if any, less valuable than that brought home by the Nares Expedition, whose object was purely scientific.

The names of Kellett, Belcher, and Austin are conspicuous by their absence, except a notice of the officer who acted as second to the latter, and who made a comparatively short sledge journey. We can scarcely suppose that the author was in any way influenced by the fact that he himself sailed in the same vessel under the immediate command of the officer whom he selects for notice, whilst wholly ignoring Admiral Austin, the chief in command.

The names of the Americans, Kane and Hayes, who with very inferior means traced *more* than 300 *miles* [1] of the unknown shores of Smith's Sound, are left out, although each was awarded the gold medal of the Royal Geographical Society—the highest honour that can be bestowed on an explorer—for their Arctic discoveries, as being the most important of the year in which they were made. These are a few examples to prove what has been said.

The author attempts to show that the system of sledging adopted by the Government Naval Expeditions is all but perfect, and that the first long sledge journeys were performed by them. Both these statements admit of question. The sledging arrangements are more or less defective in almost every particular. The tents are bad shelters, far inferior to snow-huts; the sleeping-bags are objectionable, as they prevent transmission of caloric from one individual to the other. The bag itself, being exposed all day to a temperature of perhaps 20° or 30° below zero, is so cold when the occupant gets inside, that all the moisture from the breath, &c., gets condensed upon it, making this bed after a few days' use like "sheet iron" (as remarked by a naval officer who had some unpleasant experience of the fact) and afterwards, when thawed by the extraction of most of the animal heat from the shivering tenant, becomes a veritable "wet blanket." Besides this blanket bag each man before going to rest (?) struggled into what is called a "jumper" made of thick duffle, cold as the other night-gear, thrusting the arms into the sleeves, thus keeping these unfortunate members separated by two folds of a thick non-conductor from the body that owned them, a procedure wholly opposed to both experience and science. To conserve the animal heat the Indian and white *voyageur* either take off their coats or take their arms out of the sleeves when camping out in winter. The Eskimo strips to the waist in his snow hut. It is only the naval Arctic sledge parties that act differently, with very uncomfortable results. The construction of the sledges is very defective for certain conditions of snow when in a semi-packed state—the sledge-runners then sink down six or seven inches, and have to be dragged with great difficulty *through* the snow, not *over* it. The dead weight—exclusive of food and fuel—to be hauled on this "admirable system" usually amounted to 85 or 90 lbs. per man, which weight has been reduced under another system to 35 or 40 lbs. per man without loss of efficiency.

"Long-sledge journeys," which Mr. Markham claims to have been initiated by the Government Naval Expeditions, were made at the rate of twenty miles or more a day by civilians, before the "naval system" was put in use, the first occasion of which was by the most experienced of Arctic explorers, Sir James C. Ross, in 1849, when the results were by no means satisfactory, considering the large number of men employed; a small party of five Hudson's Bay men having accomplished more than double the distance at nearly double the daily rate two years before over very difficult ice.

Mr. Markham "formulates three canons," which, he says, "are equally important, as the true methods for future Polar research," but the latter of these, namely, "to reach an advanced position within the unknown area, it is necessary to follow a coast line trending northwards, *with a western aspect*, is of most interest to the geographical inquirer."

[1] This distance (300 miles) of new discoveries is that credited to the Nares Expedition by Mr. Markham.

The four words I wish to comment upon are in italics. Had not Mr. Markham given examples of his meaning by mentioning Foxe's Channel and Regent's Inlet, I should have supposed "*western aspect*" a misprint.

It is a curious but certain fact, established by men who have been there, that the shores of all bays and inlets on the northern coast of America, the shores of all inlets and of the great islands lying north of America, having a *western aspect*, are usually ice-blocked, whilst the shores having an *eastern aspect* are comparatively free from ice and navigable. As cases in point Hudson's Bay, Regent's Inlet, Victoria Strait, the shores of Banks Land and Melvile Island, also Smith Sound,[1] are all far more ice-obstructed on the shores having a western than on those having an eastern aspect.[2]

The greater frequency of westerly and north-westerly winds and gales in the western hemisphere in high latitudes are of themselves sufficient to produce the effect I have mentioned, and to form the so-called "ancient ice" in a month or less.

The route by the west shore of Franz-Josef Land is named as favourable for getting far to the north. This may be true, but from the formation of the land it may be considered as by no means safe. The most experienced navigators of these seas state that Franz-Josef Land may perhaps be reached once in every four or five years, as the condition of the ice in Barentz Sea is very uncertain. Supposing this to be true, might not the vessel that was fortunate enough to reach these interesting islands be detained there rather longer than was either safe or agreeable? Already some not unreasonable anxiety is felt for Mr. Leigh Smith in his fine vessel manned by able icemen, who, it is believed, sailed in the direction indicated. Fortunately he is in every respect well provided to face *one* Arctic winter.

That a large quantity of heavy ice is to be generally met with in the Sea of Barentz is not difficult to account for—Spitzbergen on the west, Franz-Josef Land on the north, and Novia Zemblia on the east, form a sort of *cul-de-sac*, into which the floes appear to be drifted about by winds and currents in a most erratic manner.

Mr. Markham states that the "ancient ice" 80 or 100 feet in thickness seen by Nares and other Arctic navigators is the result of "*slow accretions*," meaning, I presume thereby, that these great ice-masses are the gradual growth of a single floe by the freezings of many winters. My opinion is that this thick-ribbed ice is the result of extreme pressure, which has forced one floe over or under the other, as in the case of the upheaval of the Austrian ship with Weyprecht and Payer in 1873-4, of which mention has already been made in the columns of NATURE.

It is doubtful if the extremest cold of an Arctic winter would have any freezing influence on the lower surface of a floe 60 or 80 feet thick, only 9 or 12 feet of which was above water, whilst the remaining 50 or 68 feet were submerged. The known effect of the action of the sea in wasting away the submerged portions of icebergs, even when these are not large, tends to support the theory I suggest. J. RAE

A Photographic Experiment with Swan's Incandescent Light

SOME trials I have recently made with Swan's incandescent electric lamps give results that may possibly interest your readers. I employed throughout an electric stream of the same energy—that generated by thirty Grove cells, and as the whole experiment lasted but an hour, it may be assumed, for all practical purposes, that the strength of the current was uniform throughout.

I made use of four lamps in all, supplied promiscuously from Newcastle, their resistances being respectively: No. 1, 67 ohms; No. 2, 59 ohms; No. 3, 58 ohms; No. 4, 52 ohms. My object was to ascertain their actinic power upon a gelatino-bromide film, individually, collectively, and in groups. To do this I exposed a gelatino-bromide film to the action of one light at a distance of 14 feet, the sensitive film being placed behind a screen more or less transparent. The screen was divided into small squares, each representing different thicknesses of fine tissue paper. Thus: square marked No. 1 represented one thickness; No. 2, two thicknesses; No. 3, three thicknesses, and so on;

[1] The author says that Sir G. Nares ascended Smith Sound having a northern trending, but he does not tell us that both on the outward and homeward voyage he kept to the shore having an *eastern aspect*—a fact.

[2] The east coast of Greenland is an exception to this rule, being ice-encumbered by the force of a well known strong current pressing the floes against it.

the last square being almost opaque, and representing twenty-five thicknesses of tissue paper. The exposure in every case was ten seconds; the distance of the film from one light or lights always 14 feet, and the number of cells 30. The development was confined to two minutes exactly, an oxalate developer of normal strength being employed [1]:—

Result of First Experiment

		No. of square through which the light penetrated.
Group of four lamps	(Nos. 1, 2, 3, 4)	13
,, three ,,	(Nos. 2, 3, 4)	15
,, two ,,	(Nos. 3, 4)	19
,, one lamp	(No. 4, low resistance)	23
,, ,,	(No. 3, high resistance)	20

As it was a matter of difficulty to judge the exact square or number printed through, the mean results of three observers or readers was taken. So that the development should be the same throughout, all plates were developed simultaneously in the same dish.

The result may not permit us to estimate with scientific accuracy the value of the lights under *the above conditions*, but it proves practically (1) that the amount of light given off by four lamps is less than that given by three, and that the electricity is employed most economically for lighting when only one lamp is used; and (2) that, at any rate in the conditions described, a comparatively low-resistance lamp gives more light than a comparatively high one.

In my second experiment I estimated the actinic power of single lamps, when one or more were in circuit, the photographic arrangements being the same.

Result of Second Experiment

	No. of square through which the light penetrated.
One lamp, No. 4 (only one in circuit)	23
One lamp, No. 4 (two in circuit)	18
One lamp, No. 4 (three in circuit)	14
One lamp, No. 4 (four in circuit)	9
Arc light (with 30 cells) ... ... upwards of	25
Ordinary fish-tail burner (burning 5 cubic feet per hour)	7

The result here is interesting in showing the comparative strength of the lamps by themselves, and to what extent the light, so to speak, is "turned down" by bringing another lamp into circuit. As my screen was only graduated as far as 25, it was impossible to estimate the comparative value of the arc light, for it went above this degree, while a low-resistance Swan lamp only goes as far as 23. This last lamp, No. 4 in the series, was the one always tested, and therefore the results shown may be considered the most favourable. The result given by a good fish-tail burner permits us to make some comparison between gas and the Swan light at a minimum.

It says something for the skill with which the sensitive gelatino-bromide is prepared commercially nowadays, when we find it is so uniformly sensitive that in the two trials (where square 23 is recorded) there should be so unanimous a result.

Sound-producing Ants

REFERRING to Mr Blanford's letter in NATURE, vol. xxv. p. 32; whilst lying awake early one morning before the servants were stirring, when camped in the Deccan at the present small station of Chota or Chick-Soogoor, on the G.I.P. Railway, during the winter of 1868-69, I heard a sound, as Mr. Blanford suggests, repeated at regular intervals of about a second. It sounded as though the wall of the tent was being struck by a light fringe along one side; but noticing that the air was perfectly still, I listened for some minutes, wondering what it was and trying to fix the locality. I got out of bed cautiously and looked out; the whole of one side of the tent for a height of two feet was covered with white ants so thickly that at the first glance I thought the wall was covered with a grey-reddish mud to this height. I was trying to make out how the sound could be produced, when it stopped suddenly, the ants evidently having become aware of my presence; they then began to clear off the wall rapidly, and in a few moments it had become white again. They had not attacked the cotton wall. On looking at the ground round the tent I found their runs extending from a tamarind tope, the nearest trees of which were about 50 feet away. The runs were built in the usual way of red Deccan soil, there were great numbers of them, varying in width from the thickness of twine to 2½ inches, often crossing each other diagonally. No doubt the ants had found the tent in the evening, and were prepared to make a morning meal of a portion of it, when I disturbed them on looking out. The impression on my mind at the time was that the whole body of ants struck the tent wall at the same time with their heads, and that it was very extraordinary that they all stopped at once; there were no dropping shots, it was an instantaneous cessation along the whole line. The tent, which was a double one, was at least 30 feet long, and the ants possibly extended round the ends. JOHN FOTHERINGHAM

UNIVERSITY COLLEGE, LONDON.—The Calendar will give you all the information you want.

"FIFTY YEARS' WORK OF THE GEOGRAPHICAL SOCIETY."—We believe Mr. Markham's narrative may be ordered through any bookseller. The Polar Observing Station at Lady Franklin Bay was really occupied by a United States party in the past summer, with the intention of carrying on observations for at least a year.

SEALS IN LAKE BAIKAL.—Mr. Edward Fry refers Mr. Keane to Bell's "British Quadrupeds," 2nd edit. p. 248, where he will find that Herr Radde figures and describes the seal of Lake Baikal in his "Reise im Süden von Ost-Siberien"; and to Murray's "Geographical Distribution of Mammals," p. 126. Mr. Thomas Ward sends the following references:—Myer's "Geography, vol. ii. p. 9, edition 1829; Erman's "Travels in Siberia," vol. ii. p. 200 (Cooley's translation); "English Cyclopædia" (Article Baikal). From this last Mr. Ward quotes as follows:—"The existence of the salmon, of the seal, and of a kind of sponge in the fresh water of the Baikal has given rise to many speculations among naturalists. Pallas and Georgi are unable to explain this phenomenon otherwise than on the supposition that the Lake of Baikal at some remote period formed a part of the Northern Ocean, . . . or on another supposition, that these animals were transported into the lake by some excessive inundation of the Lena River, whose sources are not far from its western borders."

HEADS AND HATS

WE have received the following further communications on this subject:—

HAVING last March laid the subject referred to by your correspondents, Messrs. Kesteven and Hyde Clarke, before the Bristol Naturalists' Society in a short paper, I venture to offer a *résumé* of the facts collected by my friend Dr. Beddoe and myself, which seem to justify the conclusion that a diminished size of hat is now required by young men as compared with those used by the same classes twenty to twenty five years ago. (1) I have from time to time during the last three or four years had my attention called to this alleged change by Mr. R. Castle, hatter and hosier of 1, St. Augustine's Parade, Bristol, who, in proof of it, has frequently shown me hats of small size, such as are now generally required by both gentlemen and servants between the ages of twenty and thirty. He states that these smaller hats, which used to constitute only a small percentage of his stock, now form the bulk of it, whilst those which formerly suited the larger proportion of his customers are now usually required only by the older ones amongst them. Mr. Castle estimates the difference as amounting to at least one whole size, which is equivalent to three-eighths of an inch in circumference, and he has furnished me with typical extracts from his order book to Messrs. Lincoln and Bennett in fuller proof of his assertion. I have arranged and reduced his figures in the accompanying table, and the result does undoubtedly seem to be that the buyers of 1875-80 are taking a hat at least one size smaller than the same *class* (not necessarily the same individuals) used to do twenty to twenty-five years previously. (2) My friend Dr. Beddoe, whose attention I called to the subject last year, informed me that Mr. C. Garlick, hat manufacturer of 87, Castle Street, Bristol, furnished him with the sizes of 200 hats sold by him in 1862, and the average is precisely 7, one of the lots yielding 7·01 and the other 6·99. Two

Orders for Hats from Messrs. Lincoln and Bennett in 1855, 1875, 1878, *and* 1881

Sizes.	$6\frac{1}{2}$	$6\frac{5}{8}$	$6\frac{3}{4}$	$6\frac{7}{8}$	7	$7\frac{1}{8}$	$7\frac{1}{4}$	$7\frac{3}{8}$	$7\frac{1}{2}$	Total.	Avge.		Remarks.
Circumference.	$20\frac{1}{2}$ in.	$20\frac{7}{8}$	$21\frac{1}{4}$	$21\frac{5}{8}$	22	$22\frac{3}{8}$	$22\frac{3}{4}$	$23\frac{1}{8}$	$23\frac{1}{2}$	No.	Size.		
1855		1	2	4	4	4	4	2	1	22	$7\frac{1}{16}$	$7\frac{1}{20}$	
,,				4	3	3	2			12	$7\frac{1}{32}$		
1875		2	4	6	6	4	2			24	$6\frac{30}{32}$		Average shrinkage about $\frac{1}{7}$ ('014), or rather more than one size, which amounts to $\frac{1}{8}$. Circumference of head diminished by nearly $\frac{1}{2}$ an inch.
,,		1	3	2	3	2	1			12	$6\frac{29\frac{2}{3}}{32}$		
1878		1	3	8	4	6	2			24	$6\frac{30\frac{5}{6}}{32}$	$6\frac{29}{32}$	
,,	1	3	3	3	1	1				12	$6\frac{25}{32}$		
1880		1	4	4	2	1				12	$6\frac{27\frac{1}{3}}{32}$		
,,	1	6	3	6	5	2	1			24	$6\frac{27}{32}$		These are all livery hats and are excluded from the averages.

lots of 100 each sold by him in 1880 averaged respectively 6·89 and 6·92, or a mean of 6·905. Thus the shrinkage since 1862 appears to be about 0·1 of the technical scale usually employed by the trade, of which 0·125 ($\frac{1}{8}$) represent a difference of *one size*, but a difference in the *circumference of the head* of $\frac{3}{8}$ths (= 0·375) of an inch. Therefore the above 0·1 deduced by Dr. Beddoe from Mr. Garlick's figures represents a shrinkage in circumference of over $\frac{1}{4}$ of an inch, which agrees pretty closely with my previous result of "nearly $\frac{1}{2}$ an inch" from Mr. Castle's data. (3) While in Scotland during the summer of 1880, Dr. Beddoe learned from the principal hatter in Glasgow that his experience fully corroborated what has been stated, so that the diminution appears not to be confined to the southern portion of the kingdom. (4) Mr. Mordey, hat manufacturer, of 159, Blackfriars Road, London, wrote me on February 22 as follows:—"In answer to your inquiry I beg to say that my experience tells me that men's heads have decreased in size during the last twenty years. Twenty years ago the circumference of men's heads ran from $21\frac{1}{4}$ to $23\frac{5}{8}$ inches. At the present time the size is from 21 to $22\frac{3}{4}$—mostly 21 to $22\frac{3}{8}$. This decrease is so general that we do not make big sized hats for stock, but only as ordered, and very few then." (5) Another hat manufacturer writes:—"Fifteen years ago the usual sizes of hats in England were from $6\frac{3}{4}$ to $7\frac{3}{8}$, and even $7\frac{1}{2}$ was not uncommon. But now if a $7\frac{3}{8}$ hat were wanted we should have to make a block purposely." This may be sufficient evidence to show the probable accuracy of those who assert the fact of shrinkage in the size of hats, and it only remains to add a few words as to the possible cause. To the somewhat obvious suggestion that the practice of wearing the hair more closely cropped might account for the difference, Mr. Castle, as a practical hatter, replies that the effect of this would be scarcely perceptible, and further urges that the less the head is protected by a cushion of hair, the easier must be the fit of the hat, to prevent friction and ensure comfort. The same view is taken by the manufacturer quoted in paragraph (5), who writes, "this solution of the matter is inadmissible." Another suggestion is that the mode of wearing hats has changed, and the present style admits of a smaller size. On this point Mr. J. C. Withers, hat manufacturer, of 80 and 81, Castle Street, Bristol, who has been in the trade upwards of thirty years, writes as follows:—"I am well aware that the size has considerably decreased within the last twenty to twenty-five years, but I attribute this entirely to the manner in which they are now worn, which is far more forward on the head than formerly. If I were to wear my hat as my grandfather did I should take one quite a size larger. When I was first at the trade I well remember that all hats had a cloth patch sewn on the under side of the brim at the back for the purpose of taking the friction off the coat collar, and thirty-five years ago we never made a hat without one." This explanation, I confess, sounds plausible; but though I well remember the cloth patch, so far as my memory serves it scarcely seems to me that the mode of wearing the hat has sufficiently changed within the interval (fifteen to twenty-five years) stated by the various authorities quoted to be adopted as offering a solution of the problem. In *Public Opinion* for May 28, 1881, is a letter on the subject signed "F. J.," which concludes thus: "This really does not account for the change, as hatters can testify. Twenty-five years have made little difference in the way of wearing hats, and it is during the last twenty-five years that the change has taken place." By Dr. Beddoe's kind permission I am enabled to add a curious list of the sizes of hats worn by several eminent men, which was sent to him by Mr. Garlick, who obtained it from a friend in London:—

Lord Chelmsford ..	$6\frac{1}{2}$ full.	Earl Russell	$7\frac{1}{4}$
Dean Stanley	$6\frac{3}{4}$	Lord Macaulay ...	$7\frac{3}{8}$
Lord Beaconsfield ...	7	Mr. Gladstone ...	$7\frac{3}{8}$
H.R.H. the Prince of Wales	7 full.	Mr. Thackeray ...	$7\frac{5}{8}$
Charles Dickens ...	$7\frac{1}{8}$	Louis Philippe ...	$7\frac{3}{4}$
Lord Selborne ...	$7\frac{1}{8}$	M. Julien[1]	$7\frac{3}{4}$
John Bright	$7\frac{1}{8}$	Archbishop of York	8 full.

In conclusion, to quote the remarks on my paper of a writer in the *Bristol Daily Press*, "In future the familiar expression, borrowed from Milton, of an opponent 'hiding his diminished head,' will possess a special significance. Fuller alludes, in his dissertation on 'Natural Fools,' to persons whose heads are 'sometimes so little that there is no room for wit, and sometimes so long that there is no wit for so much room,' so that, possibly, a slight diminution in the cranium is not an unmixed evil. There is, at any rate, no marked deterioration in the mental faculties, so critics may still find themselves in the position of the rustics who gazed in wonder at Goldsmith's village parson—

> "'And still they gazed, and still the wonder grew
> How one small head could carry all he knew.'"

If the diminution of heads, as well as of hats, be established, does it imply a diminution of the amount of brain, or only of the size of the cranium? F. F. TUCKETT

Frenchay, near Bristol, November 12

I BELIEVE that hatters' measurements of the head can only be accepted as mere records of the change of fashion, and that they are of little anthropological value. Thirty years ago close cropping of the hair was confined almost entirely to soldiers, grooms, and prisoners, and it was popularly considered a badge of servitude, or worse; but now, thanks perhaps to the Volunteer movement, and to the discontinuance of hair-cutting as a punishment in prisons, the military style of wearing the hair is almost universal among young men; hence smaller hats are required now than formerly. I find that long and short hair make a difference in the circumference of some heads of nearly half an inch. Again, our nightcap-wearing fathers and grandfathers were very much concerned about the temperature of their heads and ears, and they were accustomed to press their hats well down to keep them warm. Now they are worn much higher on the head, as a glance into any old print-shop window will show. Travelling-caps, and caps worn by boys, were formerly provided with lappets to cover the ears, but these peculiarities have long since disappeared, and caps of an undress military character, or felt hats, stuck on the *top* of the head, have taken their place. Mr. Hyde Clarke, in his letter in your last week's issue (p. 32), says that he has observed that the ears are lower down now than formerly, and he thinks this a proof of degeneracy of race; but the ears only appear lower because the hats are higher on the heads, and in any case it could be no proof of degeneracy, because the lower the ear the bigger the brain. But the chief reason for the falling off in the dimensions of hats in the present day is the accession to the hat-wearing community of a very large number of small-headed persons, such as clerks and shopmen, who formerly did not wear hats at all; and, on the other hand, the defection of a large-headed class, the clergy, who have given up tall hats and taken to the use of soft felt ones. The only way hatters' measurements could be made available for anthropological purposes would be to examine the statistics of one class, say the professional, who have always worn hats, and then allow for the change of fashion in the hair and the position of the hat at the present day. If it is really the case that the heads of the present generation are smaller than those of the last, we must look for the cause, not in tight-lacing, but in the diminished size or the deformity of the female pelvis, for it is this which is the gauge of the heads of the people. Male infants are longer, heavier, and have longer heads than females, and at the time of birth a greater destruction of males takes place in consequence. In Europe the proportion of infants born alive is 105 males to 100 females; but if we include the stillbirths, the proportion of the sexes is 150 males to 100 females, showing that there is a sad loss of some of the finest physical and probably mental products of our race by the mere mechanical

[1] A most remarkable head, $7\frac{3}{4}$ × $7\frac{3}{4}$.

difficulties at the time of birth. There can be no doubt that rickety conditions of town children, and the sedentary or persistent standing occupations of young girls in shops, &c., will tend to distort the pelvis, and thus act injuriously on the race by reducing both the physical and mental standard of their children. With regard to the progressive degeneracy of our population referred to by Mr. Hyde Clarke, I think something more definite than personal recollections is required to prove it. We all know how we are daily compelled to recognise the fallacy of our earlier recollections. If we go down to a country town or village, which we knew well a few years ago, we find the houses smaller, the streets narrower, and the whole place shrunken in its proportions, and it would be the same with the inhabitants also if they had stood still as the inanimate objects have done around them. There can be no doubt that our large towns are, as it were, the graves of the physique of our race, but it is not because town life is so very injurious, but because the feeble, the halt, and the blind gravitate towards them in search of work suitable to their capacities. So far from admitting the degeneracy of our population as a whole, I am satisfied that it is improving in physique, and is better now than at any former period of our history. The skill and care which saves the weak child to the community, gives health and strength to the strong, and the physique of the whole is raised to a higher level. It is difficult to find direct evidence of this improvement, but some statistics of the stature and weight of factory children (where we might expect degeneracy if anywhere), recorded in 1833 and in 1873, show that the children of the latter period were a whole year in advance of the former—children of ten or eleven years of age in 1873 being as tall and heavy as those of eleven and twelve fifty years previously. CHARLES ROBERTS

Bolton Row, Mayfair, November 11

IN a letter on the above subject in NATURE, vol. xxv. p. 8, Dr. W. B. Kesteven asks for information or opinions on the statement that English heads have diminished in size during the last twenty-five or thirty years. My own opinion is that this is really the case. On the cause of this diminution I am not at present prepared to give a decided opinion. In the course of some investigations on heredity, commenced many years ago, I discovered that in some instances the average size of the heads of the sons and daughters was less than the average of those of the two parents. In each case the former had arrived at maturity before the comparison was made, and in every instance the children had had the advantage of a much larger amount of intellectual training than the parents had enjoyed. This discovery, so contrary to all the generally accepted opinions, surprised me considerably, and caused me to make inquiries from one of the leading hat-makers in this city as to what had been his experience in the increase or diminution in the sizes of hats sold. The facts furnished to me fully confirm the statements made in Dr. Kesteven's letter, and as the hat manufacturer to whom I refer has been more than forty-five years in the business he has had ample opportunity for collecting trustworthy information. From an article subsequently published by him in a trade journal (*Umbrella and Portmanteau Trades Review*, July, 1880) I take the following: "There is another feature in connection with heads which is singular in this district, and that is the decrease in sizes. It used to be considered sufficient to make one to each dozen; we now make, on an average, three or four of these sizes, which we are now obliged to keep in stock to meet our requirements. I allude to such sizes as $6\frac{1}{2}$ and $6\frac{5}{8}$, which formerly were only necessary in boys' hats. This decrease in the size of heads has been going on for the last twenty-five years to my certain knowledge." In the letter appended to Dr. Kesteven's letter Prof. Flower asks the important question, "Does it [the statement] refer to any particular class of men, and does it refer to the same class of men?" In answer to this I have to say that the classes to which the figures in my quotation refer are, and have always been, much the same, namely, the upper and middle classes; and the individuals included in these two classes have had as much variety in their occupations as any large city, such as Manchester, can furnish. Another important question is also asked by Prof. Flower, namely, "May it (the decrease in the size of hat) not arise from some change of fashion, . . . such as hats being worn more on the top of the head than formerly." In some few instances this might possibly account for the difference, but in the majority of cases, and especially in those belonging to the dolichocephalic class of heads, it will be found that it requires quite as large a size of hat when worn more on the back part of the head as it does when worn on the top. The data already collected are probably not sufficient to base any settled opinion upon; but if more extended investigation should confirm the statements made above, it will then be a matter of some importance to us to endeavour to discover the cause of this diminution in the size of English heads. It will also be interesting to know if any such phenomenon has occurred in any other country.

Old Trafford, Manchester CHARLES H. BLACKLEY

SURELY Mr. Hyde Clarke's arguments in favour of the hatters' statements are somewhat defective. Even if the survival of human weaklings be granted, it by no means follows that a being with a weakly body must needs have a small head. Indeed the exact converse is usually accepted; for big-chested athletes are generally supposed to be the men in possession of the smaller heads, and persons of weakly constitution the possessors of the larger heads. A weakly condition of body and health is often associated with great mental activity. Besides, at birth, the conditions, if favourable for the survival of weaklings, are surely equally favourable for the strong and well-made; under ordinary circumstances then these latter individuals should show an increase in the size of the head. It cannot be imagined that the weaklings are surviving at the expense of the strong and hearty, such a case would be, as some one has said, a survival of the unfittest. It would be interesting if Mr. Hyde Clarke would tell us something more about the "old standard" in ears, when he observed ears begin to fall below this old standard, and how the old standard in ears is to be recognised. My business as an artist has caused me to particularly notice heads and faces for many years past, and from ten to thirty portraits (old and new) pass through my hands every week. My opinion, founded on this experience, entirely agrees with the statements made by some of the speakers at the meeting of the Anthropological Institute mentioned by Mr. Clarke. The alleged diminution in size of men's heads is I think due to a misinterpretation on the part of the hatters of the fact that the hair is worn much shorter now than formerly, and the hat is now worn more on the crown of the head than in the past generation. The brim of the hat brought close down over the brows and the long hair in men is a very marked feature in old portraits. W. G. SMITH

125, Grosvenor Road, Highbury, N.

I SHALL not enter into the question of the relative sizes of the heads of our generation and of that of our fathers or grandfathers, beyond stating my general agreement with the explanation suggested by Prof. Flower, viz. that we carry our hats perched on the top of our heads instead of bringing them down as they did over occiput and ears, and that many of us, myself included, wear what hair we have so short that brushes and combs become superfluities. But I must express my surprise at so eminent a reasoner and statistician as Dr. Hyde Clark giving his support to a notion that to every medical statist seems a transparent fallacy—that a reduced infant mortality implies a deterioration of the race. If the deaths of children were owing solely to exposure to the elements, there might be a survival of the fittest, and such was the case among the Highlanders in former days, as it is perhaps still among Red Indians and the like; but we know that disease does not strike or weed out the feeble ones, or the people of Liverpool and Manchester, among whom 60 to 70 per cent. die before attaining their fifth year, ought to be a more stalwart race than the Scandinavians, who lose only about 16. No! infant mortality in civilised (?) and urban populations is due to two great causes, zymotic diseases and parental neglect, including insanitary surroundings. Now scarlatina, diphtheria, &c., do not show any preference, but cut off healthy and weakly alike; and improper food, foul air, overcrowding, bad drainage, though they may kill the feebler outright, tend to deteriorate the survivors; the weak die, the strong are made weak; those who do not die of scrofula, or diarrhœa, or rickets in infancy grow up puny or consumptive—"Mox daturos progeniem vitiosorem." I maintain that just as each death registered represents two whole years of sickness, so each infant's life saved implies two who would have been feeble rendered healthy and valuable members of society. The opposite view would strike at the root of all sanitary reform.

76, Marquess Road, N. EDWARD F. WILLOUGHBY

MONO ISLAND, TRINIDAD

THE following extract from the log of the R.Y.S. *Northumbria* has been sent us for publication by Dr. G. H. Kingsley; it is dated February 28, 1881:—

"An almost perfectly land-locked harbour is formed by Monos itself and the neighbouring islands; on the Monos side indented with little bays, each one with its pretty white cottage, sparkling in the shade of clumps of coco-palms, with a silk cotton tree here and there, the latter looking as if they were trying to grow themselves into boards to save the sawyer trouble. The general tone of the vegetation just now is rather dull and New Zealandish, but the rocks along shore are covered with an infinity of bright flowers and shrubs, slender-shaped aloes bearing golden blossoms on their candelabra-like branchlets; wild pines with pink bracts and bright yellow petals, with sweet-scented orchids dangling anywhere and everywhere.

"*February* 29.—From Morrison's Bay in the hot level morning sun (most punishing and dangerous of all are the point-blank darts of Apollo), fairly into the Bocca Mono, upon the mysterious 'Guacharo,' which is here called 'watchelo.' The only cave containing them accessible at present was a low-browed one at the base of the cliff, into which an occasional roller sweeps ever and again in a most unpleasant manner, lighting up the black interior with flashes of foam, which augurs badly for the safety of our delicate pine gig. On this it was thought better to fall back on native talent, fishing close by in an island boat formed as to its lower parts of a 'dug-out' from the solid tree, and as to its upper of two planks nailed on to heighten the free board. A tituppy, ticklish kind of a craft to the inexperienced, crank in the extreme, but with a huge reputation for seaworthiness when properly handled. The negro proprietor had his head tied up in a dirty clout, in consequence of a difference of opinion with another 'cullud gebblum,' who had revenged his broken nose by literally 'mashing him jaw with rock-stone.' Though mumbly in speech, he was civil and accommodating, and taking Morrison and L. on board his dancing walnut-shell, he backed into the cave on the back of an accommodating wave. The cave was not deep enough to prevent the proceedings of those within being seen and heard by those without, and soon dismal yells, followed by smoky and smothered explosions, showed that hints were being given to the 'watchelo' to show themselves to their visitors. Another shot, followed by a jubilant shout, told us that one at least had shown himself once too often, and the party emerged blinking into the sunlight with their prey. The second entry was like the first: the interior commonplace and cavey, the interesting thing, of course, the 'watchelos,' fluttering about and perching on the more prominent projections. It is a remarkably handsome, upstanding, and even graceful bird, long-tailed, brown-feathered, with white diamond markings, just the colour of the quartz crystals in the reddish-brown rock on which it stood—a capital instance of preservative colouring, or the effect of surrounding colour. Altogether the 'watchelo' looks very much like a cross between the long-tailed cuckoo and a fair sized hawk; though the thighs are quite bare of feathers. We have been told all that is known about these queer fruit-eating Fissirostres—still there is much that is not known; for example, where they spend the night in collecting the fruit which contains the hard bristly seeds found in the stomachs of the adults and the young, and which, developing their nestlings into mere masses of fat, render them, as charming Mrs. Morrison says, '*si bon à manger.*' Mr. Morrison says that they feed on the '*Tierra firma*,' or mainland, but even he knoweth not on what.

"Having finished thus successfully our chase of the frugivorous goatsucker, we turned our attention and boat's head to another cave on the other side of the Bocca, in which dwelt an equally eccentric and out-of-the-way animal, the 'piscivorous bat.' These queer creatures, possibly in imitation of their opposite neighbours, have relinquished their supposed natural food, and have betaken themselves to catching fish at night in a manner which is not very clearly made out. Either they scoop them off the surface of the water by means of the membrane extended between their hind legs, or they catch them with their exceedingly sharp and curiously arranged claws. They dwell in a cave much more lowly and commonplace than their neighbours the 'watchelos,' and as they declined to answer the invitation sent to them by a shot into its interior, some of the party jumped overboard, mid-leg into the water, and proceeded with shouts and yells to drive them out into the glaring sunlight. Out they came in scores, these odd members of the Fishmongers' Company, flickering and fluttering in the slanting morning rays that shone through their diaphanous wing membranes and almost translucent chestnut-coloured bodies. Gnomes, Fays, Fanfullas, Flibbertigibbets, any queer, fantastic thing you have ever fancied or dreamt about, were not half so fantastic as these! Strange, and not without weird beauty to the eye. But to the nose! Fairylike in form and fluttering as they might be, the simple truth is they stank like Fitchets! 'Ruddy Miss Prue with golden hair,' in her wildest rompings, was nothing to them, and the scent produced in the hardest and strongest 'illiad' mariner a fervent desire to heave up his immortal soul. Possibly in revenge for this, the hardy one went for them with a boat-stretcher with such enthusiasm that shortly a hollow sound was heard, and another mariner, no longer enthusiastic, was observed banging his head over the gunwale of the boat, with the blood trickling down his innocent nose from as pretty a scalp-wound as ever delighted a savage. However, but little harm was done, and we collected our wounded and slain, many of which had meanwhile sunk to the bottom, and wended our way back to the *Northumbria*.

"We visited the Bocca again in a late twilight, if there be such between the tropics, to study the mode of fishing of these most mysterious bats; but it was too dark to make anything out with certainty, though the queer scooping 'swish' supposed to be produced by their skimming the surface of the water with their posterior membranes, was distinct enough. What was even more distinct was, not to put too fine a point upon it, the stink; even right out in the open Bocca and at some distance from the cave, we were aware of the neighbourhood of individuals by the heavy rank smell floated towards us in the hot evening breeze.

"It is not the slightest use the 'parlour naturalists,' who study birds in glass cases and fishes in bottles, saying that this bat, from its 'dentition,' 'tripetition,' or any other of its 'itions,' must be frugivorous or insectivorous. The simple fact is that it is neither. When you find an individual of showy exterior, but slightly imperfect manners, with his pockets full of watches with the swivels broken off, you are justified in classing him, without the slightest reference to his 'dentition,' as a specimen of the 'swell mob—Homo watch-priggious'; and I maintain that when you find the stomach of a bat—the only pocket he possesses, not being a marsupial—stuffed with the scales and bones of fishes, you are fairly entitled to put him down as 'ichthyophagous' by all the rules of common sense. Our queer friend the 'watchelo,' with his deeply-cleft bill and outstanding bristles, *ought* to be a moth-catching goatsucker; but unless he swallows seeds for ballast he certainly lives on the fruits which contained them. It is the old story: directly we find what we call 'Nature' doing a thing perfectly well in one way, we immediately find her doing it equally well in another and directly opposite one. If she finds a bird with a bill perfectly formed for the catching of moths, she at once shows that it will do equally well for picking fruits off the bushes on dark nights; and if a bat can take the smallest midge in the twilight with unerring accuracy, she turns him without alteration into as good a fisher as the very otter himself.

"I am sorry to say that the 'fish booming and drumming,' described by Charles Kingsley, was not to be heard. Either we were there at the wrong season, or the fish had been driven away by the use of dynamite. From all I heard, the sound was identical with that produced by the drum-fish so common in the Indian river of Hinda."

ROBERT MALLET, F.R.S.

THIS eminent engineer, whose researches on earthquakes are so well known to scientific men, died on the 5th inst. at the age of seventy-one. During his very active career he accomplished a vast amount of work, of which his "Earthquake Catalogue" and other published books and memoirs form the best monument.

Robert Mallet was born in Dublin on June 3, 1810. He was descended from the representative of a Devonshire family who had settled in Ireland, his father being the owner and manager of an engineer's factory. During childhood Robert Mallet appeared to be of weakly constitution, but he grew up to be a man with great powers of endurance. His taste for science was exhibited at a very early period, and before he had reached the age of twelve years he had established a laboratory in his father's house, where he delighted in performing chemical experiments. After being taught in a private school in Dublin, and making a tour on the Continent, he entered as a student at Trinity College, Dublin, and in 1830 completed his studies there by taking his M.A. degree. In 1831 he made an extended tour on the Continent, and, upon his return, married, and entered into partnership with his father. From this time forth he was busily engaged in various engineering projects both in the capital and in various parts of Ireland. Private study and research were, however, by no means neglected during these busy times, and in the very year of his commencing business we find him publishing his first paper on the motion of glaciers. He had before this time been elected a member of the Royal Irish Academy. In 1839 Mallet was elected a member of the Institute of Civil Engineers, and in the same year made his important invention of "buckled plates," an invention which was not patented till 1852, the patent being prolonged in 1866. It was in 1846 that Mallet published his first paper on Earthquake Phenomena; this memoir, which appeared in the *Philosophical Magazine*, gave a simple explanation of the supposed "vorticose movements" during earthquakes, and two years later a paper in the *Transactions* of the Royal Irish Academy contained a full exposition of his views on the wave-movement in earthquakes, with which every one is now familiar. During subsequent years Mallet published in the British Association Reports his papers, which aimed at drawing up a complete catalogue of earthquakes, with various contributions to seismology and seismometry. In 1857 occurred the great earthquake in the Neapolitan territory, and in the following year Mr. Mallet was commissioned by the Royal Society to proceed to the district and to study its effects.

The results of his observations were published in two volumes in 1862. In 1858 the Earthquake Catalogue was completed by Robert Mallet with the aid of his son, now Prof. J. W. Mallet of Virginia. About this time we find Mallet engaged in experiments upon artillery, and in calling attention to a new gun which he had invented, but which never seems to have been of much practical utility. In 1872 Mallet laid before the Royal Society a memoir, to which he had evidently, during many years, devoted much time and labour; it was entitled "On Volcanic Energy, an Attempt to Develop its True Nature and Cosmical Relations."

Whatever differences of opinion may be entertained as to the truth of the theory which is there sought to be established, there can be none whatever as to the value of the experiments which constitute its basis, or of the important influence which it has exercised upon geological thought and speculation. This important memoir, which was published in the *Philosophical Transactions*, has been translated into German by Prof. von Lasaulx, who has added a valuable commentary to it.

During the later years of his life, Mallet, who had removed from Dublin to London, was afflicted with almost total blindness, but he nevertheless continued to make occasional contributions to his favourite branches of science. Altogether he was the author of more than seventy memoirs, besides separately published works. Mr. Mallet was elected a Fellow of the Royal Society in 1854 and of the Geological Society in 1859; in 1877 he was awarded the Wollaston medal of the latter society.

THE LAND OF THE MIDNIGHT SUN[1]

UNDER the above striking title we have an account of the Peninsula of Scandinavia and of the life of its people, based on a series of journeys made at different times from 1871 to 1878, by Mr. Paul Du Chaillu. It is pleasant to meet with an author, already so well known for his travels in Equatorial Africa on new ground, and to find that his journeyings on virgin soil and among wild and savage races have not unfitted him for the study of the physical characteristics of an old country, and of the manners and customs of its inhabitants. The reader of these two handsome and well-illustrated volumes may form some notion of the extent of ground traversed during a five-years' sojourn, from the tracings of the author's routes on the map appended to the first volume. Not only was the country travelled over from north to south and from east to west, but the coast-line from Haparanda to the extreme north-eastern point of Norway, a distance of 3200 miles, was observed, the greater part of it both in winter and in summer, and over 3000 miles of fjords were sailed along. The illustrations are most frequently from photographs, but those representing Lapland winter scenes are the work of a Swedish artist.

A great many pages of this work, while pleasant reading, will not afford much new information to the reader who may have already travelled in Sweden or Norway. The route from London to Göteborg, Stockholm with its beautiful suburbs, Upsala, Christiania, Bergen, the Dovrefeld, the splendid scenes of the Romsdal; these and a few more well-known routes and places are all within the compass of an ordinary summer's tour; but Du Chaillu has told of these all in an attractive and appreciative manner, and he treats of many such only by the way as he journeys on to places seldom visited even by the sportsman in pursuit of game. He gives a good deal of interesting information about the Laplanders. The Lapps are described as kind-hearted, dirty people. Their life during summer is a very hard one. They have to follow their reindeer day and night, lest the herds should wander. Coffee was their principal drink, mixed with the thick reindeer's milk. They were a fair-haired and fair-skinned people, with blue eyes, prominent cheek-bones, and the nose *retroussé*. The men were from four feet five to five feet and one-quarter inch in height, and three women measured four feet and one-quarter, four feet and three-quarters, and four feet six and three-quarters of an inch in height respectively. It was at the Lapp village of Jockmock that Prof. Baron von Düben, so well known and appreciated in this country for his writings, was met with. He was engaged in the study of the Lapps when Du Chaillu, fatigued and hungry, found himself entering the station. Longing to see a human

[1] "The Land of the Midnight Sun: Summer and Winter Journeys through Sweden, Norway, Lapland, and Northern Finland. With Descriptions of the Inner Life of the People, their Manners and Customs, the Primitive Antiquities, &c." By Paul B. Du Chaillu. In two volumes, with map and 235 illustrations. (London: John Murray, 1881.)

face, he saw the Professor approach; and although he had never before met him, he addressed him correctly at once. He brought Du Chaillu to the neighbouring parsonage; food was soon before him, and a hearty welcome. We incidentally learn that several of the illustrations of Lapland which accompany this narrative are from original photographs taken by the talented wife of the Baron.

A Laplander's encampment would not seem to be a savoury place. A Lapp tent at its base is scarcely more than eight feet in diameter; it is very portable. The frame is composed of poles fitting into each other, easily put together, and so strong and well knit that they can resist the pressure of the heaviest storm. A cross-pole high up sustains an iron chain, at the end of which is a hook to hold kettles. Over the frame is drawn a cloth of coarse wool called "vadmal," made by the Laplanders, who never use skins; this is composed of two pieces, and is made fast by strings and pins, and well secured. A small door of canvas is suspended over the entrance. Such a tent will last more than twenty years. Some idea of its form can be obtained from the accompanying illustration. Such tents, when removed in winter, are drawn by reindeer in sledges, but in summer they have to be carried on the backs of the reindeer. Hence the moving of a Lapp encampment in summer is a very much more difficult undertaking than in winter.

The chapter on the vegetation within the Arctic circle is disappointingly short. There for some weeks there is little interruption to vegetation. What in these countries of midnight darkness can only be attempted by the aid of a brilliant electric light, is in those countries of midnight light brought about in a less artificial way. Rye planted at the middle of June was seven or eight feet high early in August, growing after first germination at the rate of three inches a day. The barley at Niavi was ready for the harvest six or seven weeks after being sown. Agricultural schools were met with all through Norway and

A Lapp Tent.

Sweden. These schools seem already to have been of enormous value to the country, raising the standard of agriculture and keeping the students up with the march of progress.

A second visit to Lapland—this time in midwinter—is described in Volume II. Entering a forest after a long drive, the author found himself suddenly in the midst of a number of holes several feet deep, dug by reindeer. Several thousand reindeer had evidently been at work. The snow was not very deep—not over four feet. Under that cover was buried the moss of which the reindeer is so fond. All except the younger ones were busy digging, first with one fore-foot, then with the other, the holes gradually becoming larger and larger, and the bodies of the animals more and more hidden. They would never stop excavating till they had reached the moss. Wherever one turned their eyes the reindeer were doing the same work, for they were evidently hungry. Their number seemed countless. Some had dug these holes so deep that nothing save the tails of the reindeer could be seen swaying to and fro outside of them.

The following extract, referring to the tame reindeer, will be read with interest:—

"Late in April and early in May is the reindeers' calving season; the period of gestation is thirty-three weeks: the little ones are either carried or put into a sleigh. When the reindeer cows call for their young they utter a peculiar grunt, which is answered by the calves. Many of the animals had already dropped their horns. The large ones resembled those of stags, but they are smaller: the reindeer is clumsier than the deer, with stouter limbs, shorter head, and a larger and wider muzzle, more like that of a cow; the hoofs are broader and much larger. The hair is grey, very coarse and thick, especially in winter, and sometimes two inches in length; the colour is much darker on the back, and almost white under the belly; the young are lighter-lined than the adults. The colour often varies considerably

among different herds, and frequently by this the ownership can be known. The reindeer are never housed, for they like cold weather and snow. Food is never given them, and they will not touch the moss that has been gathered, unless brought up to do so. They often will not even raise their heads as you approach them, and remain quiet when the Lapps pitch their tents, as we have seen. Some years prove unfavourable to their increase, on account of the amount of snow, which prevents them from digging for food; the herd then becomes weak and emaciated, and many die. The spring is also a bad time for them; the snow melts during the day, and a thick crust forms at night, so that their feet break through, causing lameness and disease. The horns of the males, which often weigh forty pounds, attain the full size at the age of five or six years, those of the cow at about four years. The time of dropping the horns in a herd varies from March to May; in the adult animal they attain their full size in September or at the beginning of October. After the age of eight years the branches gradually drop off. The shoulder-blades appear a little high, occasioning a slight hump or protuberance. Without the reindeer the Laplander could not exist in those northern regions: it is his horse, his beast of burden; it affords him food, clothing, shoes, and gloves. Domestic reindeer are a curious admixture of wildness and tameness. In some respects they are greatly superior to other cattle; in a herd they are very easily managed; they usually keep close together, and in the winter season remain where they have been left to feed. When on the march, with the help of dogs, they go in a solid mass, and a herd does not scatter unless wolves are after them; but in summer they often wander a long distance when left by themselves, as is often the case. When harnessed they become uneasy and distrustful, and great caution has to be taken not to startle them. Often trained reindeer, like horses, become refractory or vicious, and very difficult to manage, and then the Lapp shows his skill. The speed of the reindeer varies very much according to the time of the year, October, November, and December being the months in which they are fleetest, as then they are fresh from their summer pasture; the cold weather strengthens them, and they are not exhausted from digging the snow, not yet very deep, to procure their food. The rapidity of their gait depends much on the state of the surface. If this is well packed or crusted, and if previous furrows have been made, they go very fast. Much depends too upon the distance, and whether the country is hilly or not, with a long range of slopes. On the rivers, over well-packed snow and a good track, the animals can go twelve or fifteen miles the first hour, and down a long mountain-slope twenty miles, and even more. They can travel five or six hours without stopping, the first hour rapidly, the second more slowly, and towards the fifth or sixth quite slowly, for by that time they require rest and food. Early in the winter, when they are in good condition, one can travel with a swift reindeer one hundred and fifty miles in a day, where the country is not very hilly and the way good, and easily enough one hundred miles. The colder the weather the greater is the speed: seventy or eighty miles is a good average, but they were slow at the season of which I write."

Reindeer digging in the snow.

The chapter on the Lofoden Islands gives a great deal of information about the extensive fisheries of cod, in which over 700 fishing-boats are employed.

We had marked several other extracts relating to the domestic life of the Norwegian peasants in the high north, and to the interesting people of Dalecarlia; but enough has been given to show our readers that, while the narrative of these travels is free from the exciting scenes witnessed in Gorilla Land, it is not wanting in much that will be read with pleasure and remembered with profit.

NOTES

We take the following from the *Times*:—The medals in the gift of the Royal Society for the present year have been awarded by the Council as follows:—The Copley medal to Prof. Karl Adolph Wurtz of Paris, For. Mem. R.S., for his discovery of the organic ammonias, the glycols, and numerous other investigations which have exercised considerable influence on the progress of chemistry; the Davey medal to Prof. Adolf Baeyer of Munich for his synthesis of indigo; a Royal medal to Mr. Francis Maitland Balfour, F.R.S., of Cambridge, for his numerous and important contributions to animal morphology, and more especially for his investigations respecting the origin of the uro-genital organs and the cerebro-spinal nerves of the vertebrata, and for his work on the development of the elasmobranch fishes; a Royal medal to the Rev. John Hewitt Jellett of

Dublin for his various mathematical and physical papers, more especially for his researches in chemical optics and his invention of the new and delicate analyser by which they were carried out.

THE Bakerian Lecture at the Royal Society will be given next Thursday by Prof. Tyndall, on the "Action of Free Molecules on Radiant Heat, and its Conversion thereby into Sound."

THE election to the Linacre Professorship of Physiology in Oxford University will take place on the 25th inst.

M. PAUL BERT, the eminent Professor of Physiology at the Sorbonne, has been appointed French Minister of Public Instruction by M. Gambetta. Two hours only after his nomination had been signed by the President of the Republic he read before the Academy of Sciences an elaborate paper on "Chloroform and other Anæsthetics." This may be considered as a token of the interest that the new French Government mean to take in scientific matters. M. Cochéry, of the Post and Telegraph Department, is the only member of the old Cabinet who has taken office in the new one.

IN view of the great and kindly interest the United States have always taken in English Arctic expeditions, the Council of the Geographical Society have determined to urge H.M.'s Government to undertake an expedition next year in search of the *Jeannette*. It being obviously more easy for the Americans than for this country to send an expedition by sea on the side of Behring Strait, it is thought that it would be best to despatch a party along the Great Mackenzie River to search the coast-line that can be reached from it, and that such work might most advantageously be carried out through the agency of the Hudson Bay Company. Under these circumstances it will be necessary to open communications with the Colonial Office on the subject.

THE authorities of the Crystal Palace sent out on Saturday the allotments of space to the principal exhibitors of electric light at the forthcoming exhibition. If the various electric lighting companies and firms carry out their intentions, the palace will be lighted from the London, Brighton, and South Coast Railway Stations to the north end. The applications from intending exhibitors in other classes than that of lighting will be attended to this week, and it is hoped that the allotments will be issued on Saturday or Monday next.

THE Chinese authorities have recently recalled a large number of students from Hartford College, U.S., under somewhat peculiar circumstances. The youths had been specially selected in China to undergo a thorough course of instruction in various branches of knowledge in the United States. They were placed under the charge of Mr. Yung Wing, who at one time held a high diplomatic post at Washington, and whose knowledge of the language and country led to his selection for this purpose. A large building for their accommodation was purchased by the Chinese Government near Hartford, and every thing seemed to be going on well. Much surprise was therefore expressed when, long before the termination of their course of study, the young men were suddenly recalled, and by this time they have all reached China. It appears that a high official of the Government, on his passage through America to Europe, examined the institution where his young countrymen were being trained. He was alarmed to find they were being rapidly Americanised, and that some had gone so far as to part with their pigtails, and dress in foreign garments. He thought also that he noticed a growth of ideas in their minds which, however congenial to a republic, were out of the question in China; that the youths' minds would gradually be alienated from their native country, and that the impressions which they were imbibing might lead to trouble and disaffection in China. He accordingly wrote to Peking, recommending the recall of the mission. His views were immediately adopted; but it is hoped that the students will not lose much, as they are about to be sent to European countries, to which the same objections do not exist as to the United States. The incident shows very clearly that, however anxious the Chinese may be for the science and knowledge of the west, they want none of its political doctrines.

ON Tuesday a deputation, consisting among others of Lord Harberton, Sir Antonio Brady, the Hon. Rollo Russell, Capt. Galton, C.B., Col. Festing, R E., Prof. Chandler Roberts, F.R.S., Mr. Ernest Hart, Mr. George Shaw, and Mr. W. R. E. Coles, waited upon the Lord Mayor at the Mansion House, and asked him to open the exhibition and trials of smoke-preventing appliances now about to be held at South Kensington. The earnest effort, they said, of the Committee had been to encourage general improvement in the methods and appliances by which heat was obtained, and thus to secure the advantages of greater economy of fuel and lessened smoke. That effort had been so far successful that a very considerable number of economical and effective grates, stoves, and furnaces had been brought forward, and many improved methods of firing and other smoke-preventing means had been introduced. The Lord Mayor acceded to the request of the deputation, and the Committee promised to communicate with him as to the day of opening the exhibition, which will probably be about the end of the month.

THE English Royal Commission on Technical Education have, the *Times* correspondent states, been busy in Paris in visiting the higher, the secondary, and the primary schools. and particularly those in which manual and technical instruction is provided. It is their intention to inquire into the state of instruction in the districts in which cotton, woollen, and silk manufactures are carried on, and also in some of the chief pottery manufactories abroad, and to ascertain what resources are available for the same purpose in the corresponding manufacturing districts in England—an inquiry which they have already commenced by visits to Yorkshire and Staffordshire. During the winter they will continue to study the condition of technical instruction in the English manufacturing districts, and in the spring it is their intention to visit Germany, where the chairman, Mr. Samuelson, on a late visit to Berlin, has already set on foot some preliminary investigations.

THE banquet in honour of Prof. Virchow is to be held at Berlin on the 19th inst., in the Rathhaus, and promises to be highly brilliant and successful. The sum of 30,000 marks, originally proposed to be raised for the memorial, appears likely to be greatly exceeded. This memorial will consist of a marble bust of the Professor, and will be placed in the hall of the Pathological Institute on the above-mentioned day, in commemoration of his twenty-five years' labours as a teacher of medical science.

THE *Morning Post* states that, among other experiments now being conducted by a chemist at the Royal Short-horn Dairy at Dytchleys, Essex, the powers of carferal, already well known as a filtering medium in the removal of ammonia from sewage, are being investigated. It has been found that all ammonia is taken up by the carferal, as is indicated by testing the fluid after it has passed through it, and the resultant is a material valuable in breaking up and manuring heavy land.

THE Nürnberg Natural History Society recently made an excursion to Berg near Neumarkt (Upper Palatinate), and upon this occasion a large number of Teleosaurus bones (vertebræ and others) were found at the boundary between brown Jurassic and Lias. Besides these fine specimens of Belemnites, Ammonites. and Terebratulæ were found. The bones in question are of course completely petrified; the impressions of the scaly hide on the back are well preserved. All the objects found are now deposited in the Society's collection.

THE Pesth correspondent of the *Daily News*, telegraphing on the night of the 9th inst., states that Agram has again experienced a violent shock of earthquake. Shocks of earthquake, sufficiently severe to occasion considerable alarm, were felt at Château d'Oex, Canton Vaud, on Wednesday night and Thursday morning last week. The second of the shocks, which appear to have been altogether local, was accompanied by loud rumblings. There were three slight earthquake shocks in various parts of Switzerland last month, all local, and affecting only a very limited area. The first occurred at Monthey, in the Valais, on October 14; the second at Berne, on October 17; and the third at Zürich, on October 27. A violent earthquake was felt on October 27 at 10.30 p.m. in the northern part of the canton of Zürich. On the same day at 4.30 a.m. a slight shock was felt at Cilli and several other places in Styria.

THE death is announced of Dr. Eduard Simon Heine, Professor at Halle University, an eminent mathematician. He died at Halle on October 24 last.

WE regret to announce the death of Dr. Carl Arendts of Munich, a well-known geographer, and founder of the Geographical Society of that city. Dr. Arendts died at Possenhofen on October 11, aged sixty-seven years. He was the author of numerous standard works, and editor of the excellent *Deutsche Rundschau für Geographie und Statistik*, which has just commenced its fourth volume.

OUR readers are aware that Dr. Kobelt visited North Africa and Spain last spring, by the assistance of the Rüppell Institution of Frankfort, in order to investigate the molluscous fauna of the two countries, as well as to gather evidence bearing upon the question how far the land-connection between the two countries extended in bygone ages. He now reports that it may safely be assumed that the connection was not confined to the Straits of Gibraltar, but extended at least as far as the meridian of Oran and Cartagena. Dr. Kobelt will publish the detailed results of his investigations in the malacozoological journal, of which he is the editor.

THE Gotha Natural History Society will arrange an exhibition of natural history and geographical objects from November 20 to December 20. The Duke of Saxe-Coburg Gotha has lent the Society a suite of rooms in the Castle for this purpose.

A TUNNEL through the Col de Somport, near the Pic du Midi, in the Pyrenees, is the next large engineering work which will be undertaken in France. It will shorten the railway distance between Paris and Madrid by 100 kilomètres, the Spanish line passing by way of Ayerbe, Caldearenas, Jaca, and Confranc, leading on the French side into the Gave de Aspe valley and Oléron.

WE have before us the prospectus of a new entomological monthly journal, to be styled the *Wiener entomologische Zeitung*, of which the first part is to appear at the beginning of 1882, each part to consist of a sheet and a half of text, large 8vo. The editors are Ludwig Ganglbauer, Dr. Franz Löw, Prof. Josef Mik, Edmund Reitter, and Fritz Wachtl, all of Vienna, and it will be published by Alfred Hölder of that city. With so strong a staff it should prove a success. In some respects it is intended as a successor to the for many years defunct *Wiener entomologisches Monatsschrift*.

MR. LEO LESQUEREUX, we learn from the Harvard Library *Bulletin*, No. 3, has made a preliminary Report on the Plants of the Dakota Group collected by Mr. Sternberg for the Museum of Comparative Zoology (to be published in the *Museum Bulletin*). He says the collection is valuable in regard to the data it furnishes in confirmation of, or contradiction to, some of the general conclusions derived from the examination of the materials formerly described from this peculiar Cretaceous flora. For example, the disconnection of the flora of the Dakota group from that of the older zones—those of the Jurassic times—does not appear now so positive as formerly, or as it was indicated in the Cretaceous Flora Reports of Hayden's Survey. On the other side, the disconnection of the Cretaceous flora from that of the Lower Tertiary appears now still more evident, as the new species do not indicate any affinity with the plants of the Laramie group, which is positively Eocene by its types. Mr. Lesquereux is inclined to explain the distribution of the fossil plants of this group over small areas, as showing that the trees apparently grew around small hillocks or dry surfaces of land disseminated in wide lagoons. If derived from distant shores the leaves should be more or less mixed, while a comparison of the different localities shows that the fossil leaves were derived from trees grown in the places where they are now found fossil.

THE complete annihilation of Elm, according to the Geneva correspondent of the *Daily News*, appears to be now only a question of time and a little bad weather. At the request of the Government, Prof. Heim has just made another inspection of the Tschingel. He finds the work of disintegration proceeding much more rapidly than he expected. The entire summit of the Risikopp, the peak nearest Elm, is in movement, and its fall is not likely to be long delayed. It may miss the village, but the chance is very remote. The inhabitants remain meanwhile in their houses, which they have not to quit until the sentinels who are watching on the mountain warn them that danger is imminent.

IN Japan, according to a recent return, there are in all 159 hospitals where the patients are treated on the principles of western medicine. Thirty-five of these are private institutions in the sense that they receive no government aid, while twelve are naval or military hospitals. The remainder are scattered throughout the country; but they are said to be, in the remote districts, in a very crude condition. Vaccination, which is compulsory, is performed *gratis* everywhere. A law prohibiting the practice of physic or surgery by any except persons holding certificates of permission has recently been passed. A large school of medicine, with German professors, has been established for the past eight or ten years in the capital.

AT Nagy-Look (Hungary) the remains of a two-wheeled Roman car were lately discovered, with the skeletons of two horses attached to it. The objects are believed to date from the third century, and the place where they were found to have been the tomb of the owner. All the parts of the carriage are of most exquisite workmanship.

THE Russian Government intend to construct a canal between the Dnjepr and Düna Rivers, the Orschitsa, a tributary of the Dnjepr, to form a part of the canal. The distance by water between the Euxine and the Baltic would thus be shortened by 415 versts.

A ROUMANIAN mechanic, Traiano Feodoresen, recently submitted to the Chamber at Bucharest a project of a submarine vessel, and after examination of this by a committee the Government was authorised to meet the expense of construction. The vessel is to be capable of moving under water, at a depth of 30 metres, for twelve hours, without requiring renewal of air. Steam is the motor, and the speed is quicker than that of sailing vessels. The vessel is simply sunk by opening certain valves, but return to the surface requires more complex operations. An electric light will render objects distinguishable at 30 or 40 metres. For renewal of air it is not necessary that the vessel rise to the surface; an apparatus can be sent up, which, by actuating a pump, forces air into suitable receivers.

It is often supposed that the reality of alchemy, the transformation of the base into the noble metals, was generally accepted by orientals. But, according to Herr E. Wiedemann (*Ann. der Phys.* No. 10), some of the most noted *savants* rejected the idea. In his Prolegomenon, Ibn Khaldûn maintains that the transformation of metals is impossible, the philosopher's stone cannot exist, and the study of alchemy is ruinous. His own views, however, interest us less than his citation of Avicenna and his school as opponents of alchemy. While Abu Nasir al Farâbi, an older philosopher, held that all metals belong to the same species, and differed only in accidents, so that a transformation of these into each other was possible, Avicenna maintained that the metals differed in species, and that their specific differences, ordained by God, were therefore not alterable by chemical operations. A noted alchemist, Togair, contended, against this, that the task of alchemy was not to impart these differences to metals, but only to alter the latter so that they might be enabled to acquire them; the means to this being the elixir. A great predecessor of Avicenna, Al Kindi, also appears to have opposed alchemy.

The additions to the Zoological Society's Gardens during the past week include two Vulpine Phalangers (*Phalangista vulpina*), a Rufous Rat Kangaroo (*Hypsiprymnus rufescens*) from Australia, presented by Mr. F. J. Horniman, F.Z.S.; a Ring-necked Parrakeet (*Palæornis torquata*) from India, presented by the Countess Dowager of Lonsdale; two Long-eared Owls (*Asio otus*), British, presented by the Rev. J. A. Wix; two Grey Wagtails (*Motacilla sulphurea*), British, presented by Mr. Swaysland; a Dufresne's Amazon (*Chrysotis dufresniana*) from South-East Brazil, a Yellow-cheeked Amazon (*Chrysotis autumnalis*) from Honduras, an Orange-winged Amazon (*Chrysotis amazonica*) from South America, deposited; a Pluto Monkey (*Cercopithecus pluto*), a Sykes's Monkey (*Cercopithecus albogularis*) from West Africa, a Darwin's Rhea (*Rhea darwini*) from Patagonia, a Picazuro Pigeon (*Columba picazuro*) from South America, two Spotted Zenaida Doves (*Zenaida maculata*) from La Plata, two Dominican Gulls (*Larus dominicanus*) from Antarctic America, purchased.

EXPERIMENTS ON COLOUR[1]

In a former paper with the above title (NATURE, vol. iii. p. 234) I described some combinations of absorbing media capable of transmitting the red and green, while stopping the other rays of the spectrum. In this way I obtained a *purely compound* yellow, made up of red and green, and free from homogeneous yellow light. In devising such combinations we have in the first place to seek an absorbing agent capable of removing the yellow of the spectrum, while allowing the red and green to pass. For this purpose I used an alkaline infusion of litmus, or solution of chloride of chromium, placed in a trough with parallel glass sides. In order to stop the blue rays we may avail ourselves of chromate of potassium. If a second trough be not objected to, it is best to use the bichromate, as exercising the most powerful absorption upon the upper end of the spectrum; but the bichromate cannot be mixed with litmus without destroying the desired action of the latter upon yellow. In this case we must content ourselves with the neutral chromate.

During the last year and a half I have resumed these experiments with the view, if possible, of finding solid media capable of the same effects, and so of dispensing with the somewhat troublesome troughs necessary for fluids. With this object we may employ films of gelatine or of collodion, spread upon glass and impregnated with various dyes, gelatine being chosen when the dye is soluble in water, and collodion when the dye is soluble in alcohol. Thus in the case of litmus a slightly warmed plate is coated with a hot and carefully filtered solution of gelatine, allowed to remain in a perfectly horizontal position until the gelatine is set, and then put aside to dry, by preference in a current of warm air. The films thus obtained are usually somewhat rough upon the surface, so that I have preferred to use two pieces cemented together, coated sides inwards, with Canada balsam. In conjunction with the litmus we may employ a silver-stained orange glass, and so isolate the red and green rays. For the orange glass Mr. C. Horner has substituted a film of collodion stained with aurine. Samples possibly vary; but that which I have used, though extremely opaque to the blue green rays, and therefore so far very suitable for the purpose, allows a considerable quantity of the higher blue to pass. By spreading aurine upon a pale yellow glass, I obtained a very perfect absorption of the blue-green and higher rays. Plates prepared as above described answer the purpose very well; but I have found that in some cases the litmus in contact with the balsam becomes slowly reddened, the action creeping inwards from the edge. A dye, capable of replacing litmus, and free from this defect, is "soluble aniline blue," whose absorption, as I found rather unexpectedly, begins in the yellow and orange. Bichromate of potash and aniline blue may be mixed in the same solution, and there is no difficulty in so adjusting the proportions as to secure a good compound yellow. To obtain solid films gelatine must be used, as in the case of litmus, for the dye is not soluble in collodion. With aniline there is no difficulty from the Canada balsam, and two plates cemented together answer perfectly.

For systematic observations on compound colours nothing probably can be better than Maxwell's colour box in its original form; but it seemed to me that for the examination of certain special questions a more portable arrangement would be convenient. In an instrument of this class a full degree of brightness requires that the width of the eye-slit, placed where the spectrum is formed, should not contract the aperture of the eye, *i.e.* should not be less than about one-fifth of an inch; and although the maximum of brightness is not necessary, considerations of this kind largely influence the design. If we regard the width of the eye-slit as given, a certain length of spectrum is necessary in order to attain the desired standard in respect of purity of colour; so that what we have to aim at is a sufficient linear extension of the spectrum. A suitable compromise can then be made between the claims of brightness and purity.

The necessary length of spectrum can be obtained by increasing either the angular dispersion of the prisms or the focal length of the lens by which the image is formed. If portability be no object, the latter is the preferable method, and the focal length may well be increased up to five or six feet; in this way we may obtain a field of view of given purity of colour and of maximum brightness, at the expense only of its angular extent. If, however, we desire an instrument which can be moved from one place to another without losing its adjustment, the focal length of the lenses must be kept down, and then a large prismatic dispersion is the only alternative.

Increased dispersion can of course be obtained by multiplication of prisms; but for the purpose in view, high resolving power is not wanted, and our object may be attained with a comparatively small total thickness of glass, either by the use of higher angles than usual, or by giving the light a more nearly grazing emergence. The latter was the course adopted in designing the first instrument of which I have to speak. A pair of prisms of 60°, cut from an ordinary single $1\frac{1}{4} \times 1\frac{1}{4}$-inch prism along a plane bisecting at right angles its refracting edge, were arranged in the corner of a shallow box, so as to form what Thollon calls a *couple*. Considered as a simple, rigidly connected refractor, the pair of prisms are placed so as to give minimum deviation, but the incident and emergent light makes smaller angles with the final surface, than if each prism were adjusted separately for minimum deviation. The collimating and focussing lenses are common spectacle glasses of about 8" focus. The box is $12'' \times 12'' \times 3''$. Light entering at a slit on one of the sides of the box would be turned by the prisms through an angle rather greater than a right angle, and throw a pure spectrum upon another side of the box. This side is cut away, and provided with movable screens of cardboard, so that any part may be open or closed as desired. When the eye is applied to the first slit, the prisms are seen uniformly illuminated with colours whose composition depends upon the situation and width of the slits between the cardboard screens through which light is allowed to enter. In this way we may obtain a uniform field of view lighted with any combination of spectral colours. My object, however, was to obtain an instrument for making comparisons between the simple and compound yellow, and for this purpose an addition was necessary. This consisted

[1] Read before Section A of the British Association, September 2, 1881, by Lord Rayleigh, F.R.S.

of a very acute-angled prism held close to the dispersing prisms in such a position that its refracting edge was horizontal, dividing the field of view into two equal parts. The action of this prism is most easily understood by again supposing the light to enter at the eye-slit. Half of the light proceeds as before, forming ultimately a pure spectrum upon the side of the box. The upper half of the beam, however, is deflected by the acute-angled prism, and the corresponding spectrum is thrown upwards, so as to lie somewhat higher upon the side of the box. This part is also cut away, and provided with movable screens. By the principle of reversibility the consequence is that an eye placed at the first slit sees *two* uniform patches of colour, the lower formed as before by light from the lower set of slits, the upper, covering the acute-angled prism, by light from the upper set of slits. These colours are in close juxtaposition, and may be compared with ease and accuracy.

The great difficulty in this class of instruments is to devise any efficient and reasonably simple method of controlling the position and widths of the slits. In the present case I contented myself with strips of blackened cardboard cemented to the side of the box with sealing-wax, or soft wax, according to the degree of permanence of adjustment aimed at. One part of the field was illuminated with homogeneous yellow (about the line D) from a single slit. The other half was lighted with a mixture of full red and full green, and the observation consisted in adjusting the widths of the slits through which the red and green were admitted, until the mixture was a match with the simple yellow.

The first trials of this instrument in the spring of last year revealed an interesting peculiarity of colour vision, quite distinct from colour blindness. The red and green mixture which to my eyes and to those of most people matches perfectly the homogeneous yellow of the line D, appeared to my three brothers-in-law hopelessly too red, "almost as red as red sealing-wax." In order to suit their eyes the proportion of red had to be greatly diminished, until to normal sight the colour was a fair green with scarcely any approach to yellow at all. So far as could be made out at the time, the three abnormal observers agreed well among themselves, a fact which subsequent measurements have confirmed. It appeared afterwards that a fourth brother was normal as well as the three sisters.

These peculiarities were quite unexpected. After the fact had been proved, I remembered a dispute some years before as to the colour of a dichromatic liquid, which appeared to me green, while one of my brothers-in-law maintained that it was red; but the observation was not followed up, as it ought to have been, each of us, I suppose, regarding the other as inaccurate. After the establishment of the difference I determined to carry out a plan, which I had tried with success some years before (October 1877), for a colour-mixing arrangement depending on double refraction, by which I hoped to obtain an easily adjustable instrument suitable for testing the vision of a number of persons.

In my original experiments I used a 60° doubly refracting prism of quartz, which threw two spectra of the linear source upon the screen containing the eye slit. These oppositely polarised spectra partially overlapped, and by suitable placing of the prism could be made to furnish red and green light to the eye. By the rotation of a small Nicol held immediately behind the eye slit, the red or green could be isolated or mixed in any desired proportion. One advantage of this arrangement is that the two component lights come from the same slit, so that we are less dependent upon the uniformity of the light behind; but it is perhaps a greater merit that the adjustment of proportions is effected by simple rotation at the eye slit, allowing the observer to try the effect of small changes with ease and rapidity.

In the new instrument, which was completed during the autumn of last year, separate prisms were used to effect the dispersion and double refraction. For the sake of compactness, a direct vision prism by Browning, containing two flints and three crowns, was chosen, in conjunction with a small achromatic double image prism. At one end of a long narrow box, 24″ × 2″ × 2″, the light is admitted through a slit whose position and width can be adjusted by sliding its jaws along a divided scale. After travelling about $9\frac{1}{4}''$ it falls upon the double image prism mounted upon a small table so as to allow of rotation, and then after two more inches upon a collimating lens, by which the two beams are rendered parallel. Next comes the dispersing prism, and then the focussing lens, throwing pure spectra upon the other end of the box, which carries the eye slit. The distance between the two lenses is $3\frac{1}{2}''$, and the entire length of the box is about 24″. The eye slit is a fixture, and immediately behind it is the rotating Nicol, whose position is read by a pointer on a divided circle.

The parts of the spectrum from which the component lights are taken can be chosen over a sufficient range by use of the two adjustments already mentioned. By rotation of the table on which the double image prism is mounted, the separating power is altered, and one spectrum made to slide over the other, while by moving the entrance slit the spectra are shifted together without relative displacement.

It yet remains to describe the parts by which the comparison colour is exhibited. Between the double image prism and the collimating lens a small vertical reflector is mounted on a turn-table at an angle of about 45°. Its dimensions are such that it covers the lower half of the field of view only, leaving the upper half undisturbed, and its function is to reflect light coming from a lateral slit through the dispersing prism so as to throw a third spectrum upon the eye. The lateral slit is carried in a small draw tube projecting about 2″ from the side of the box, and the light proceeding from it is rendered nearly parallel before reflection by a lens of short focus. No adjustment is provided for the position or width of the lateral slit; all that is necessary in this respect being attainable by rotating the mirror and by varying the brightness of the light behind. As sources of light I have found Argand gas flames, surrounded by opal globes, to be suitable. The gas tap supplying the lateral flame is within reach of the observer, who has thus the means of adjusting the match both with respect to colour and with respect to brightness, without losing sight of the subjects of comparison. The zero of the divided circle corresponds approximately to the complete exclusion of green, but readings were always taken on both sides of it so as to make the results independent of this adjustment. The circle is divided into 100 parts, green being excluded at 0 and 50, and red at 25 and 75. Tenths of a division could be estimated pretty correctly, an accuracy of reading fully sufficient for the purpose, as the observations of even practised observers would vary two or three-tenths.

It is evident that the numbers obtained are dependent upon the quality of the light by which the principal slit is illuminated. In order to avoid errors in the comparison of different persons' vision arising from this source, it is advisable always to take simultaneous observations from some practised individual whose vision may be treated as a standard; but no evidence appeared of any variation in the quality of the gaslight. The special application of such instruments to the comparison of the qualities of various kinds of mixed light was alluded to at the end of my paper "On the Light from the Sky," &c. (*Phil. Mag.*, April, 1871).

I have obtained matches between simple and compound yellow from twenty-three male observers, principally students in the laboratory. Of these sixteen agree with myself within the limits of the errors of observation. The remaining seven include my three brothers-in-law, and two others, Mr. J. J. Thomson and Mr. Threlfall, whose vision in this respect agrees very nearly with theirs. The vision of the other two observers differs from mine in the opposite direction. In one case the difference, though apparently real, is small, but in the other (Mr. Hart), though there was some difficulty in getting a good observation, the difference is most decided. Among seven female observers whom I have tried, there is not one whose vision differs sensibly from my own.

Although the number examined is insufficient for statistical purposes, it is evident that the peculiarity is by no means rare, at least among men. As far as my experience has gone, it would seem too as if normal vision were not of the nature of an average, from which small deviations are more probable than larger ones; but this requires confirmation. In order to give a more precise idea of the amount of the difference in question, I have calculated from the laws of double refraction the relative quantities of red and green light required by Mr. F. M. Balfour and myself to match the same yellow light. If we call R and G the maximum brightnesses of the red and green light (as they would reach the eye if the Nicol were removed), and r, g the actual brightnesses (as modified by the analyser) necessary for the match, then for Mr. Balfour—

$$r/g = 1\cdot50\ (R/G),$$

while for myself—

$$r/g = 3\cdot13\ (R/G).$$

In other words, Mr. Balfour requires only half as much red as myself, in order to turn a given amount of green into yellow.

The corresponding numbers for the other four observers of this class would be substantially the same. On the other hand, Mr. Hart requires much *more* red than I do in order to convert a given green into yellow—in the ratio of about 2·6 : 1.

Except in the case of Mr. Hart, the colour vision of these observers is defective only in the sense that it differs from that of the majority. Their appreciation of small colour differences is as distinct as usual. In order to test this Mr. G. W. Balfour made a complete series of colour matches with revolving disks in the manner described by Maxwell and in my former paper. Six matches, of which only two are really independent, were observed, the consistency of the set being a measure of the accuracy of observation. The average error proved to be only double of that which I have found in my own observations, and rather less than that usually met with in the case of observers whose vision is normal.

In connection with what has been described above with respect to trichromic vision, it is interesting to notice that corresponding and perhaps larger differences are to be found in the vision of the so-called colour-blind. The double-refraction apparatus may conveniently be used in this investigation. With the pointer adjusted to 0 or 25, we have in the upper half of the field pure red or pure green respectively, and in the lower half pure yellow as usual. By suitable adjustment of the gas taps two observers of this class, Mr. T—— and Mr. B——, are able to obtain perfect matches both between red and yellow, and between green and yellow, but the proportions necessary are very different for the two observers. In Mr. T——'s red and yellow match, the red is to normal vision dazzlingly bright, and the yellow almost too dark to be recognised; while the green and yellow match, however extravagant as to hue, appears reasonable in respect of brightness. On the other hand, to Mr. B——'s eyes, the red of the spectrum does not look nearly so dark, and the equivalent red and yellow appear to the normal eye to be much more nearly upon a level. Although these great differences exist, there is no doubt that the vision of both observers is strictly dichromic, and that, apart from brightness, all the rays of the spectrum, from red to green, have the same effect upon their eyes.

If we wish to go beyond the fact that this vision is dichromic, and inquire whether the case is one of red blindness or of green blindness, we must be careful to consider whether the question itself has a definite meaning. If trichromic vision were always the same, and if a particular case of colour-blind vision differed from it merely by the absence of the red sensation, that vision would intelligibly be characterised as red-blind. There is reason to believe that such cases exist. In all probability the suppression of my own red sensation would lead me to make matches very nearly the same as Mr. T——'s; and in this sense he may fairly be called red-blind. But under the same circumstances my matches would be altogether rejected by Mr. B—— ; and the question may be asked, whether his case, being certainly not one of simple red-blindness, can be brought under the head of green-blindness. To this the sufficient answer is that if I became green-blind my matches would differ from those of Mr. B—— far more than if I was red-blind. The test of green-blindness would be the possibility of matches between colours which to normal eyes appear green and purple, or green and grey. Although a good deal has been said lately on this subject, I am not aware of a case in which accurate matches of this kind have been obtained from observers whose colour-vision is in other respects acute. If such cases exist, inquiry should be instituted, in order to see how far the matches would correspond to green-blindness of an otherwise normal eye.

We see, then, that there is dichromic vision which cannot accurately be described as affected with red-blindness, and still less as affected with green-blindness. The difference from normal vision, being not simply one of defect, cannot be defined by any single phrase. To obtain a complete knowledge of it quantitative observations over the whole spectrum, such as those carried out by Maxwell, are necessary. It is fortunate that these observations are easier to arrange for dichromic than for trichromic vision.

That I might be able to form an opinion upon the general acuteness of his colour vision, Mr. T—— was good enough to observe a series of five colour matches between red, white, blue, green, and yellow, one being left out each time. The results are given in the accompanying table; those marked "calculated" being a consistent set derived by elimination from the two marked A and B. The good general agreement of the two sets of numbers is a proof that within its restricted range Mr. T——'s sense of colour is acute. The first observation in which a mixture of red and white is matched by a mixture of green and blue is the most characteristic.

	Red.	White.	Blue.	Green.	Yellow.	Dec. 2, 1880.
(1)	76·2	23·8	−23·3	−76·7	0	Observed
	77·4	22·6	−21	−79	0	Calculated
(2)	56·6	43·4	−52·3	0	−47·7	Observed
	56·2	43·8	−52·5	0	−47·5	Calculated
(3)	68·2	5·5	0	−100	26·3	Observed
	69·7	6·5	0	−100	23·8	Calculated
(4)	60·3	0	8	−100	31·7	Observed
	61·2	0	7·8	−100	31	Calculated
(5)	0	32·5	−43·5	67·5	−56·5	Observed
	0	32·3	−44·1	67·7	−55·9	Calculated
A	522	424	−511	35	−470	—
B	641	405	−470	−199	−377	—

In conclusion I will describe an apparatus by which it is possible to observe these colour-matches without rotating the disks. At the time of my first experiments, about ten years since, I was struck with the advantage which might ensue if it were possible to have the mixed colours in view during the time of actual adjustment, and I thought of a plan by which this object might be attained. The idea, which I carried out soon afterwards, was to spin an *image* of the disks instead of the disks themselves. An inverting prism was mounted in a tube which could be made to rotate. The axis of rotation is adjusted so as to point accurately to the centres of the disks mounted as usual. An eye applied to the prism sees the disks undisplaced as a whole, but inverted by reflection. As the tube rotates, the image of the disks rotates also, and with double angular velocity. When the speed is sufficient, the colours lying on any circle concentric with the disks are blended exactly as if the disks themselves revolved.

This apparatus is quite successful; but its real advantages of working at a smaller velocity, and of allowing adjustment while the rotation continues, are counterbalanced in practice by the inconvenience of having to look through a tube, and the uncertainty introduced by the possible disturbance of the match due to unequal illumination of the area occupied by the disks.

MAGNETIC DISTURBANCES, AURORAS, AND EARTH CURRENTS [1]

THE object of establishing a magnetic observatory is to determine at any instant the direction and magnitude of the earth's magnetic force. The direction of the magnetic force of the earth is the direction in which a small magnetic needle would point when it is freely suspended, so as to turn about an axis passing through its centre of gravity. But it is not easy to suspend a magnetic needle so as to turn freely and yet to be sure that the axis about which it turns passes accurately through the centre of gravity of the needle, and if it does not so pass, then on suspending the needle we have not only the magnetic force but also the gravitating force of the earth acting upon it to turn it about its axis, and the position which it takes up shows us the direction of these combined forces upon the magnetic needle.

This direction depends upon the mass of the needle, for to that its weight is due; it depends upon the form of the needle and the position of its centre of gravity with regard to the axis on which it is hung; it depends also on the magnetic properties of the substance, so that it is not easy to determine even the direction of the magnetic force by a plan which theoretically is so very simple. Instead of attempting to make the required determinations by such a method it is necessary that a steadier mode of suspension should be adopted, and that may be done as soon as it is discovered in what vertical plane the force of gravity,

[1] Lecture delivered at the Royal Institution on Friday evening, June 3, 1881, by Prof. W. Grylls Adams, F.R.S.

combined with the earth's magnetic force, will cause such a needle to rest. This is usually done by loading a steel needle at one end and then magnetising it with its poles so arranged that the extra weight of the heavier end shall balance the downward pull of the magnetic force on the other end. In this case the needle when magnetised will remain at rest in a horizontal direction, when suspended on a point on which it can turn freely in a horizontal plane.

A magnetic needle suspended in this way has been called a declination needle. Such a needle is employed in the mariner's compass, in our galvanometers for measuring currents of electricity, and in magnetic observatories for determining the declination or what is sometimes called the variation of the magnetic needle. This needle determines the position of the vertical plane in which lies the direction of the earth's magnetic force; this is called the plane of the magnetic meridian. The plane of the *magnetic* meridian is usually different from the vertical plane through the north and south poles, which is called the geographical meridian, and the angle between these two planes is the declination or variation of the magnetic needle.

If such a magnetic needle as I have just described be supported on horizontal knife edges instead of being supported on a point, the needle when magnetised may remain at rest balanced in a horizontal direction, one end being pulled downwards by the earth's vertical magnetic force, and the other by the force of gravity. Any change in the intensity of the vertical magnetic force of the earth will be shown by an up or down motion of the marked end of the needle. Such an instrument, called a balance magnetometer, is specially adapted for showing any changes in the vertical magnetic force of the earth, and the changes or disturbances of the earth's *vertical* magnetic force are determined by means of such a balance magnetometer. We have then our declination or variation needle to determine the vertical plane, called the magnetic meridian, and we have our balance magnetometer to determine any changes which may take place in the vertical magnetic force of the earth.

By the declination needle we can not only determine the plane of the magnetic needle, but by making the needle oscillate to and fro horizontally and counting the number of oscillations in a given time we can determine the horizontal pull upon the poles of the needle, *i.e.* the intensity of the earth's horizontal magnetic force upon the needle, just as by the swing of a simple pendulum in a vertical plane under the action of the force of gravity we can determine the pull of the force of gravity upon the bob of the pendulum. By a similar method and by a properly suspended needle either the vertical force or the total magnetic force of the earth may be determined.

In order then to determine the direction of the earth's magnetic force we may make use of a declination needle to give us the vertical plane, and place the dipping needle in such a position that it will oscillate in that plane; when it comes to rest it will point in the direction of the total magnetic force, *i.e.* in the direction through the room of Faraday's lines of magnetic force.

In order to determine the magnitude of that force the horizontal force may be found by finding the number of oscillations of the declination needle in the way that I have already explained, and these three determinations will give us the direction and magnitude of the earth's total magnetic force.

Another method of making the required determinations is to take a coil of copper wire, which is wound on a circular frame in such a way as to be capable of spinning on a diameter of the circular frame.

Faraday showed that on turning such a coil in a mag etic field a current of electricity is induced in the coil, and the strength of this current is proportional to the number of lines of force cut by the coil. We may describe such an arrangement as a magneto-electric machine, in which the magnet employed is the earth itself.

By means of this instrument we may determine either the horizontal or the vertical magnetic force f the earth. By placing the axis vertical and spinning the coil at a given rate we may determine the horizontal force, and by placing the axis horizontal in the magnetic meridian and spinning the coil at the same rate we may determine the vertical force, the currents produced in the two cases being in the same ratio as the numbers of the lines of force cut in the two positions.

The greater the angle at which the axis of rotation is inclined to the direction of the lines of force the greater will be the number of them included in the revolving circle, and the greater the induced current produced in the coil.

Thus placing the axis in different positions we get currents of different strengths, and may readily see that we get the greatest current when the axis is at right-angles to the direction of the lines of force, *i.e.* to the line of the dip

We may further make use of such a coil to find the direction of the lines of force, for if we place the axis parallel to the lines of force, the currents in opposite halves of the coil will balance one another, because each line of force is cut twice by the coil, and so no current is produced in the external circuit through the galvanometer.

If then we place the coil so as to get no current when we rotate it, then the direction of the axis of the coil is the direction of the dipping needle, *i.e.* of the magnetic lines of force.

We will suppose now that for some point of time, say June 1st at 12 o'clock midday, the three magnetic elements, *i.e.* the declination, the horizontal force, and the vertical force, have been determined, we have now to consider the changes or disturbances produced in these magnetic elements, and the connection of these changes with other phenomena, and especially the connection between auroras, earth currents, and the larger and more irregular magnetic disturbances.

I have already drawn attention to the declination needle and the balance magnetometer for measuring the changes of declination and of the vertical force.

For measurement of the changes in the horizontal force a special instrument is employed, called a bifilar magnetometer, in which a magnet is suspended by two threads, which are so placed that by their torsion acting against the magnetic force of the earth, the magnet is kept at rest in a horizontal position in a direction at right angles to the magnetic meridian.

This completes the list of instruments for our magnetic observatory.

Any change or disturbance of the horizontal force pulls this magnet round more or less in the horizontal plane, and its change of position is observed as in the other instruments. The results I have to bring before you this evening have been derived from the photographic registrations of similar instruments in different parts of the world, so that the motion of the needle has recorded its own tale on the prepared paper which is wrapped on a cylinder driven by clockwork, and so placed as to receive the spot of light reflected by the moving needle.

First, there are regular daily and yearly changes, showing that the sun produces regular changes in the three magnetic elements which depend on the time of the day and the season of the year, so that the change of position and apparent motion of the sun with respect to the place of observation produce regular magnetic changes. These regular daily changes are accompanied by and have very generally been supposed to be due to electric currents or electric waves traversing the earth's crust, and a discussion by Dr. Lloyd of the observations made by Mr. Barlow in 1847 of currents on telegraph wires showed a very close relationship between the two-hourly changes of the declination needle and the changes of intensity and direction of earth currents on telegraph lines.

Both Dr. Lamont and Dr. Lloyd conclude from their comparisons of earth currents and magnetic changes that the changes of the declination needle cannot be due to the direct action of the electric current traversing the earth's crust, but that these currents or waves, extending to a considerable depth, alter by induction the magnetism of the earth itself, and this change of magnetism causes the observed changes in the declination needle. Thus the magnetic changes are the indirect effects of (not the earth current in its immediate neighbourhood, but of) a change in the magnetism of the earth itself, which may be due to an electric wave extending over a considerable area of the earth's surface.

The point towards which the total earth current is directed follows the sun and seems to lag two or three hours behind, but not the same distance behind at different places.

These earth currents have been ascribed to different causes: thus Dr. Lamont regards them as the results of electric force emanating from the sun; De Saussure regards them as developed by evaporation, the vapour being positively charged, and the water being negative; Dr. Lloyd regards them as effects of solar heat; whilst M. de la Rive ascribes them to chemical actions going on in the interior of the solid crust of the earth, the electricity being transported into the atmosphere by evaporation.

Mr. Ellis of the Greenwich Observatory has shown the intimate relation between solar action and the regular diurnal

magnetic changes of declination and horizontal force at Greenwich Observatory during thirty-five years from 1841 to 1876 by a comparison of the observations of those elements. The results of his observations are shown on a large diagram which has been enlarged from his curves, and they show what a close relationship exists between solar storms and terrestial magnetic changes. There are not only daily and yearly periods of the variations of the different magnetic elements, but there also seems to be in the horizontal intensity a period of twenty-five or twenty-six days, which is the time of rotation of the sun on his axis. Other recent investigations have shown that these regular magnetic changes depend not only on the sun, but that they are also in part due to the action of the moon, and these portions depend upon the length of the lunar day and on the position of the moon with regard to the earth. Just as there are regular earth currents whose direction depends upon the sun, which we may call the solar earth currents, so there are lunar earth currents which go through their changes under the action of the moon, and it has been shown that the effects are produced not immediately under the moon, but there is a lagging behind in the case of the lunar earth currents, just as in the case of the solar earth currents. In the case of the lunar earth currents we cannot attribute the production of the electricity either to heat or to thermo-electric currents from one part to another of the earth's crust, and we must therefore look for some other source. May we not find it in the fact that the moon causes tides in the solid crust of the earth, just as she causes tides in the oceans? The earth's crust is made up of elastic materials and materials capable of yielding and altering their form to a considerable amount with the change in the direction of the pull of the moon upon them. This crust also contains magnetic substances in abundance which alter their form under the moon's attraction, and so from the changes of position of masses of magnetic matter changes are produced in the magnetism of the earth which must give rise to induced currents of electricity or earth currents. Let us imagine a conductor of electricity outside the earth, stretching from the North Pole to the equator and fixed in space, with the earth, a magnetic body, revolving beneath it from west to east; then it follows, from Faraday's laws of induced currents, that the revolution of the earth on its axis would cause a current in the fixed conductor in a direction from the pole to the equator.

If the conductor moved over the surface of the earth from west to east, and the earth did not revolve, or revolved at a slower rate, then the current in the conductor would be from the equator to the pole. The current depends upon the relative motion of the earth and the wire. If then we have an insulated wire running north and south, the tides in the earth's crust, of which I have spoken, will be equivalent to a lagging behind of magnetic matter, and so we may expect in that wire a current of electricity whose general direction would be from the equator to the pole. The position of the wire with reference to the magnetic pole of the earth would modify the direction of these earth currents, and it is quite conceivable that the position of England with regard to the magnetic pole might cause these regular earth currents to be greatest in the south-west and north-east direction. The lagging of the lunar earth currents behind the position of the moon would also be accounted for by the lagging of the tides behind the moon. If this is a true cause for some portion at least of the lunar earth currents, then the same reasoning applied to the sun may in a smaller degree apply to the case of the regular solar diurnal earth currents, and may help to account for the lagging behind of the effects due to the sun, so that the fact that the greatest solar effect happens about 2.30 p.m. may not be entirely due to the fact that that is the hottest part of the day, but may also in part depend upon the tides.

We have now to consider those more sudden changes of the suspended magnets, which are distinguished by the name magnetic disturbances. In 1874 Dr. Lloyd said of them:—"The duration and the magnitude of these oscillations are as yet outside the domain of law, and probably depend upon so many operating causes that, like the gusts and lulls of the wind in an atmospheric storm, they will long baffle all attempts to refer them to their actuating forces, or even to reduce them to order."

Certain facts relating to these disturbances have long been known. From the series of observations started by Gauss in 1834, and made every five minutes at the same times at a variety of places, at first in Europe and afterwards in various parts of the world, the disturbing power was found to increase in northern latitudes; also it was made out that the appearance of a disturbance in several places occurred at the same time, but there were great differences in the results at different places.

In Europe the agreement was very good, and also in America; but the agreement between Europe and America was not so satisfactory.

The force seemed to originate in a certain point in the interior of the earth, and the direction of the disturbing force seemed to be constant: yet sometimes there were great differences in the deviations at places not far apart, and from the result of his observations Weber was led to believe that there was a centre of disturbances which was somewhere in the neighbourhood of St. Petersburg.

However sudden and unconnected single disturbances may seem to be, they still follow certain laws in their occurrence; Sabine found that they had daily and yearly variations from their mean values, and that they have an eleven-year period, which agreed with the eleven-year period of the appearance of spots upon the sun.

Disturbances are more frequent in summer than in winter, and this applies to each hemisphere; and it has been confirmed by various observers that they are also subject to the influence of the moon. Lamont says of these disturbances, "Their cause is a force which is subject to certain laws but which does not act constantly; the mean direction and frequency have yet to be discovered."

Observations have shown that the magnetic disturbances and electric currents on the earth are so nearly related to one another that people naturally look upon the electric currents, either in the crust of the earth or in the atmosphere outside it, as the cause of the magnetic disturbances. These currents in the earth have usually been attributed to changes of temperature, because they also are found to be in some way governed by the sun.

Now let us come to more recent observations of magnetic disturbances with the improved methods of recording observations by photography which are now available. For some years past photographic records have been taken of the magnetic elements, but the curves have been laid aside, and very little use has been made of them; so much so that some three or four years ago a circular letter from Mr. Ellery, Director of the Melbourne Observatory, was sent round to those scientific men who were supposed to be interested in the matter to know whether it was advisable to continue the photographic records of magnetic changes at Melbourne, which is the most southern station, and the only station in the southern hemisphere except Mauritius, where such observations are taken. Mr. Ellery did not for one moment suppose that they were of no value, but as no use was made of them he wished to know whether the money expended might not be better applied to another purpose. This matter has been taken up by the Kew Committee, of which Dr. De La Rue is the chairman, and a recommendation was made that the directors of all observatories which possess instruments of the Kew pattern should be invited to send to Kew their photographic records, or careful tracings of them, for a given period, so that a comparison might be made of the results.

The period chosen was the month of March, 1879, and records for the whole month have been sent from Lisbon, Coimbra, Stonyhurst, Vienna, St. Petersburg, and Bombay, in the northern hemisphere, and from Melbourne and the Mauritius in the southern hemisphere.

A preliminary account of a comparison of the declination curves from the European stations was brought before the British Association last year at Swansea, and this evening I have to bring before you some further points which come out of these comparisons. Let us take the disturbances on March 15-16, 1879, which will illustrate some of the points which I wish to bring out prominently.

Not only do magnetic changes occur at the same time at different stations, but there is a great similarity between them.

It must be remembered that at northern stations the horizontal force is smaller in proportion to the whole force than it is at stations nearer to the equator, so that the same disturbance will produce less effect on the horizontal force or on the declination needle in latitudes near the equator.

Also the needles at different stations are by no means in the same state of sensibility, and even at the same station they change with time, so that they are not always equally sensitive, and when they lose their magnetism they have to be re-magnetised.

We see that soon after 10 a.m. G.T. on March 15, 1879, there is a disturbance wave showing first a diminution and then an

increase in the horizontal force at St. Petersburg, Vienna, Kew, and Lisbon. At Melbourne in Australia there is a similar disturbance at the same time both in the declination and in the horizontal force.

Again, between 2 and 3 and between 4 and 5 p.m. there are very small disturbances showing themselves at the same absolute time in the horizontal force and declination curves. About 5.20 p.m. there is a well marked increase in the horizontal force and eastward deflection of the declination needles. About 9.30 p.m. G.T. a storm begins which lasts for about an hour. It is felt in the northern and in the southern hemispheres, near to and on both sides of the equator. At all European stations the horizontal force is increased during the first part of the storm, and then diminished.

At Lisbon the vertical force is first increased and then diminished, and at St. Petersburg and Stonyhurst there is a diminution in the vertical force at the same time as at Lisbon. If we regard the declination needles, we find that at St. Petersburg, Zi-ka-Wei, and Melbourne, and at Bombay, the declination westward is first increased and then diminished, whereas at Kew and Lisbon the motions are in the opposite direction.

The declination at Vienna seems to be intermediate between Kew and St. Petersburg, but the curve is incomplete.

At Bombay and the Mauritius, near to but on opposite sides of the equator, the declination needles are deflected opposite ways. The local time at these places was from 1 to 2 o'clock at night.

Now in what way can we account for such magnetic disturbances as this? If we assume that by magnetic induction from some cause or other the earth's magnetism is altered, then the position of the magnet which would produce the disturbance must be such that its pole which attracts the marked end of our needle must lie at the beginning of the disturbance to the east of Kew and Lisbon, to the north of Vienna, and to the north-west of St. Petersburg; the Lisbon vertical force curve also shows it to be below the surface of the earth. Hence an inductive action equivalent to a change of position of the north magnetic pole towards the geographical pole would account for these changes. The strengthening and weakening of a magnet with its north pole to the north on the meridian of Vienna might possibly account for the magnetic changes observed between 9.30 and 10.30 at night, Greenwich time, on March 15, 1879.

If we attempt to explain this disturbance by currents of electricity or discharges of statical electricity in the air above the needles, then we must imagine that at first there is a strong current from the south-west over St. Petersburg, from the west over Vienna, and from the north-west over Kew and Lisbon, the vertical force needle at Lisbon showing that the current from the north-west lies somewhat to the east of Lisbon, that at the Mauritius this current is from the north, and at Bombay from the south.

Hence we must imagine that a current of electricity passes down from north-west to the south-east, going on towards the east over Vienna, and towards the north-east over St. Petersburg. This must be kept up very much along the same line throughout the first part of the disturbance, and then the current or currents must be altered in strength in the same manner at all stations.

We will next consider what would hardly be called a magnetic storm, but a few very small deviations of the magnetic needle, lasting from about 5.30 to 7.30 p.m. on March 26, 1879. Only the comparison of the originals will give the closeness of the similarity of the curves, and the curves for Vienna and Kew are absolutely coincident.

When the declination needle is deflected to the west, the horizontal force needle is deflected with its marked end towards the south, so that in this disturbance the two needles are drawn towards the south-west at the same time with greater or less power, and twelve similar bends are clearly traced out in the Vienna and Kew curves during the two hours. These disturbances are all so very small, that but for the comparison of photographs they would probably be lost sight of; yet we see that the same deflections occur at the same instant at Kew and at Vienna, at St. Petersburg and at Melbourne. From the remarkable similarity in these disturbances and their occurrence at the same time, we should expect that the cause of disturbance is so far removed from the places of observation that the difference of their distances from it need not be considered. This might not unreasonably be urged as an argument in support of a theory that such disturbances are due directly to the action of the sun regarded as a magnetic body. The numerical comparisons of observations made every five minutes on certain days previously fixed upon would probably never have shown the way in which these minute changes of magnetic power of the earth at widely distant places are related to one another.

In one or two cases Señor Capello and Prof. Balfour Stewart had compared the Lisbon and Kew curves for a particular disturbance, but the photographic magnetic records have never before been collected from other stations, and there has been no opportunity of comparing them. From the precise similarity of the forms of the curves in many cases we may say that the *rate of change* of magnetic disturbances at widely distant stations is the same. There is nothing fitful or flashing in such disturbances as these of March 26. We might imagine a current in the crust of the earth or a current or transfer of electricity in the air near to, *i.e.* within twenty or thirty miles of each of these observatories, but to imagine the same current and the same variations of the current at so many different stations, all changing in the same way at the same instant, is difficult, unless it can be shown in what way all these changes are connected with the cause of such a regular electric discharge. It seems easier to imagine that such changes as these are due to a change produced by induction in the magnetism of the earth itself by some distant body. It is easy to show that the magnetism produced by a current in a magnetic substance round which it flows is greater in its action on a small magnetic needle than the direct action of the current itself. Hence a current flowing in the crust of the earth should produce its principal effect on a magnetic needle by the magnetic induction which the current induces in the earth itself.

Sometimes disturbances occur where at the same instant there are similar deflections of the declination needles at stations wide apart, and suddenly at one of the stations the needle no longer goes with the others, but begins to go, and continues for a considerable period to go, in the opposite direction to the others, turning when they turn, and tracing out a similar curve, but turned always in the opposite direction. Such cases occurred frequently during March, 1879, and especially on March 23, about 1.30 and about 7 p.m., Kew time, and on March 29, about 9 p.m. An examination of the principal disturbances seems to show that:

(1) A diminution in the horizontal force is accompanied by greater easterly deflections of the declination needle at St. Petersburg than at Kew.

(2) Increase of the horizontal force is accompanied by greater westerly deflections at St. Petersburg than at Kew, or is sometimes accompanied by a westerly deflection at St. Petersburg and an easterly deflection at Kew.

These cases which I have taken will be sufficient to show how important it is that there should be additional magnetic observatories, especially in the southern hemisphere, where photographic records should be taken, so that we may learn something about the magnetism of the earth. Practically we have to rely on one excellent observatory (Melbourne) for the whole of the southern hemisphere. Surely the time has arrived when there should be photographic registration of the magnetic elements at such an important observatory as the Cape of Good Hope, especially when the French Government has decided within the last few weeks to establish a magnetic observatory at Cape Horn. With observatories at Melbourne, at Cape Horn, and at the Cape of Good Hope, the southern hemisphere would be well supplied, and probably the Russian Government would then soon establish an observatory in the east of Siberia.

Now we can readily show the way in which the magnetic instruments are disturbed in a magnetic observatory by the alteration of the strength of a magnet. Taking magnetic needles to represent the declination needle, the inclination needle, and the bifilar or horizontal force needle, we may place an electro-magnet in a given position with regard to them, and by altering the strength of that electro-magnet may cause these needles to trace out disturbances of a very decided character. In the disturbance of March 26 the greatest motion of the needle was not more than about 2′ of angle at Kew or at Vienna. It would not be possible for me to show you the action on so small a scale.

I have as yet been speaking of only moderate disturbances, but now let us come to some of the larger ones, and I have had the opportunity, through the kindness of the Kew Committee, and the observers at the various observatories mentioned, of studying the curves for the August magnetic storm which began at 10.20 a.m. Greenwich time, on August 11th, and for convenience may be divided into three storms, one lasting from 10.20 on the 11th, to 1 a.m. on the 12th; a second from 11.30 a.m. on the 12th to

7.20 on the 13th; and the third from 11.50 a.m on the 13th to 7 to 8 a.m. on the 14th of August.

I have prepared a large sheet, on which these curves have been copied as accurately as possible for the first of these storms on the 11th. For this storm I have also the curves from Toronto and from Zi-ka-wei. The first storm began on August 11 at the same instant at all the stations. There is a decided similarity, especially in the horizontal force curves, throughout the first part of this storm, and certain points in it stand out prominently. At Kew, the beginning of the storm is not actually recorded, because the sheets of prepared paper on the time cylinders were changed precisely at 10 20 a.m. when the storm was beginning. The deflections are alike at Lisbon, Kew, Vienna, St. Petersburg, and after the very first sudden deflection, at Toronto also. The greatest effect is produced at St. Petersburg; the similarity between the large disturbances at Vienna and at Toronto in Canada, places differing about 6½ hours in time, is remarkable. About 11.45, 1 p.m., and 2.40 p.m., there are very remarkable points of agreement.

From about 4.30 p.m. to 8 p.m. Greenwich time, *i.e.*, from about 11 a.m. to 2.30 p.m. Toronto time, the deflections are opposed at Toronto, and at Vienna or Kew.

This would rather point to solar action as the cause of disturbance. In this case the Kew curve is not so much deflected as the Vienna curve, because the horizontal needle at Kew is not nearly so sensitive as at Vienna, and the relative strengths of the actual disturbing forces at the two places can only be obtained by comparison of the scale-values at the two places.

I will draw your attention to one other point on this day. At 9 p.m. the disturbances are all in the same direction, but about 11 p.m., whilst St. Petersburg agrees in direction with the others in a very violent phase of the storm, at Toronto the direction of the deflections is reversed, and this reversal of curves continues until about the end of the first of the three storms.

The second storm, beginning about 11.30 a.m. on the 12th, and lasting until the next morning, was the most remarkable of the three. It not only baffles the telegraph clerks, who wish to keep out earth currents from their lines, but it even goes beyond the powers of the magnetic observatories which are specially designed to watch over them. Thus, at Toronto, the line goes off the edge of the paper on which the photographic record is taken. At Melbourne the motion is so rapid, and also at Vienna, that the plate is not sensitive enough to receive the impressions; the motion is too quick even for photography. At the time of greatest disturbance, about 12.20 midday, it is very remarkable that at Lisbon, and at Zi-ka-wei, near Shanghai in China, two places nearly in the same latitude, but nearly nine hours apart in time, the vertical force is increased in precisely the same way and to the same amount at the same instant.

At Zi ka-wei in China, the sudden change in the horizontal force on the needle amounted to about $\frac{1}{10}$th part of the total horizontal force, and at St. Petersburg the change in the horizontal force amounted to $\frac{1}{30}$th part of the horizontal force, and the total force was changed by about $\frac{1}{80}$th part of its full value.

Hence, any cause for these magnetic changes, in order to be a true and sufficient one, must be capable of producing such intense magnetic changes as these all over the surface of the earth. These magnetic changes are so large as to be quite comparable, as we see, with the earth's total force, so that any cause which is shown to be incompetent from the nature of things to produce the one can hardly be held to account for the other.

Since, as I have shown, the large disturbances and the small disturbances do not follow totally different laws, but agree equally well all over the earth, in so far as they agree we must attribute them to the same cause.

During this August storm, as also during the remarkable storm of January 31 last, great difficulties were experienced in working the telegraph lines, and Mr. Preece has been kind enough to send me particulars of these storms.

I am also greatly indebted to the Astronomer-Royal for sending me traces of the earth-current photographic records taken at Greenwich Observatory during the August storm on two separate wires, one running from the north-east, and the other from the south-east, to Greenwich. The two tracings are bent opposite ways at the same time, so that when a current was running on one line towards Greenwich, on the other it was running away from it, and comparing these curves with the earth-current records from Derby and Haverfordwest and other places, it appears that the general direction of currents during this storm was from south-west to north-east, or from south-south-west to north-north-east, with varying intensity, the agreement being very close between the disturbances of the declination needle and the Blackheath and Greenwich photographic record. From Mr. Preece's record also earth-currents were violent from 10.30 a.m. on the 11th (*i.e.* they were noted within ten minutes of the beginning of the magnetic storm) to about 2.30 p.m., and again from 9 to midnight.

They were very violent on August 12, beginning at 11.30 a.m., the beginning of the second storm, and quieting down about 4.30 p.m., then beginning again at 7.30 and lasting until 9.30 p.m.

Again on the 13th they are strong for 1½ hours, from about 5 in the morning, *i.e.* just about the end of the second magnetic storm.

The general direction of the earth-currents as observed at Derby or Haverfordwest, as well as at Greenwich, was from north-east to south-west.

Again on January 31 last another violent magnetic storm occurred, in which the currents were even more violent than in the August storm.

Intimately connected with magnetic disturbances and earth currents is the phenomenon of the aurora or polar light, which is an electric discharge in the upper regions of the atmosphere. During the August and January storms the aurora was well seen in England; it was also seen at St. Petersburg, and as far east as Siberia. It does not appear to have been seen, although it was looked for, at Zi-ka-wei in China by M. Dechevrens, the director of the observatory, although the magnetic storm was so violent there that the horizontal force was suddenly changed by $\frac{1}{10}$th part of its total amount.

We may arrive at some idea of the character of the aurora by studying electric discharges in vacuum tubes, and Dr. De La Rue has already brought this subject before you in his Friday evening lecture.

We may gradually pass from electric discharges in air of ordinary density, in which we get the well-known electric spark between two surfaces, to air of less density but better conducting power, and then to air of less density still, but of such high resistance that no electricity will pass. Dr. De La Rue has shown that with 11,000 cells of his battery the striking distance between two points is about six-tenths of an inch in air of ordinary density of about 760 mm. pressure.

When the pressure in a hydrogen tube is reduced to 21.7 mm. 8,937 cells will cause a discharge to take place through thirty inches.

When the pressure is reduced to ·642 (about six-tenths of a mm.), 430 cells will cause a discharge through the tube.

When the pressure is still further reduced to ·0065, it requires 8,937 cells to cause the discharge, so that the spark passes more readily at a pressure of ·642 mm. than it does at a higher or a lower pressure. This is also the case with air.

The lower regions of the earth's atmosphere offer great resistance to the passage of electricity, but as we ascend the pressure diminishes and the electric resistance diminishes, until at last, at a height of between thirty and forty miles, a level is reached where the air offers least resistance to the passage of electricity, where the pressure is about ·397 of a mm., and above that level the electrical resistance again increases, so that at a height of about eighty miles the battery of 11,000 cells would not cause a spark to pass.

If we take a tube which has not been very highly exhausted we see that the light from the positive pole extends nearly through the tube, and the dark space around the negative pole is small. As the exhaustion proceeds and the pressure of the air is diminished, the electric spark passes through greater and greater lengths and changes its character, until we get to the pressure corresponding to the least resistance. Beyond that the resistance increases, the dark space around the negative pole expands and the molecules fly about more freely; those on the negative plate being charged with electricity, and being repelled from it proceed for a long distance in straight lines, and possess the power of causing bodies on which they strike to glow. In Mr. Crookes's tubes we get very beautiful effects from this glowing of the glass tube itself, or from the glowing of substances in the path of the stream. We may regard this as a stream of molecules of gas charged with electricity, and we see the difference between this stream and the electric current in a vacuum tube at lower exhaustion by the action of the magnet upon it. In one case the current going through the molecules from pole to pole in the tube is bent out of its course by the magnet, and symmetri-

cally by the two poles, and returns to its path, the line of least resistance, through the molecules, whereas the stream of molecules at the higher exhaustion, carrying their electricity with them, are carried away by the electric charge upon them, and get utterly lost and scattered on striking the side of the tube, yielding up a great deal of energy in the form of heat to the tube or to the glowing platinum or other substance in the tube.

I must now show you the beautiful aurora tube which has been seen once in this theatre, and for which I am indebted to the kindness of Dr. De La Rue. It has been brought to the right state of exhaustion to show just those effects which will help better than any description of mine to give you an idea of the character of the aurora discharge in the middle regions of the atmosphere.

By bringing a magnet to bear upon this discharge we may see the effect of terrestial magnetism on the aurora discharges in the atmosphere.

Aurora Borealis.—The aurora as seen in the north-eastern parts of Siberia, where it is often very brilliant, is described as consisting of single bright pillars rising in the north and in the north-east, gradually covering a large space of the heavens; these rush about from place to place, and reaching up to the zenith, produce an appearance as if a vast tent was spread in the heavens, glittering with gold, rubies, and sapphires.

More exact attempts have been made to describe the aurora, and perhaps I may be allowed to quote Dalton's description of an aurora as seen by him.

A remarkable red appearance of clouds was noticed in the southern horizon, which afforded light enough to read by, and a remarkable effect was expected. He says, "There was a large luminous horizontal arch to the southward, and one or more concentric arches northward. All the arches seemed exactly bisected by the plane of the magnetic meridian. At 10.30 streamers appeared in the S.E. running to and fro from W. to E.; they increased in number, and approached the zenith, when all of a sudden the whole hemisphere was covered with them, and exhibited such an appearance as baffles all description. The intensity of the light, the prodigious number and volatility of the beams, the grand intermixture of all the primitive colours in their utmost splendour, variegating the glowing canopy with the most luxuriant and enchanting scenery, afforded an awful, but at the same time a most pleasing and sublime spectacle. But," he adds, "the uncommon grandeur of the scene only lasted one minute. The variety of colours disappeared, and the beams lost their lateral motion, and were converted, as usual, into the flashing radiations; but even then it surpassed all other appearances of the aurora, in that the whole hemisphere was covered with it."

In his address before the British Association in 1863, Sir William Armstrong speaks of the sympathy between forces operating in the sun and magnetic forces on the earth, and notices a remarkable phenomenon seen by independent observers on September 1, 1859

"A sudden outburst of light, far exceeding the brightness of the sun's surface, was seen to take place, and sweep like a drifting cloud over a portion of the solar surface. This was attended with magnetic disturbances of unusual intensity, and with exhibitions of aurora of extraordinary brilliancy. The identical instant at which the effusion of light was observed was recorded by an abrupt and strongly-marked deflection in the self-registering instruments at Kew. The magnetic storm commenced before and continued after the event."

The daily and yearly periods of the magnetic changes, the change in the horizontal force depending on the sun's rotation on his axis, the agreement of the eleven-year period of magnetic disturbances, sun-spots, and auroras, show that the sun plays a very important part in causing or governing both the regular and irregular magnetic changes.

If the sun be assumed to be a very powerful magnet, then changes in his magnetism might be expected to affect the magnetism of the earth, although the effect could not be very large, unless the sun is magnetised to an intensity much greater even, compared to his mass, than the earth is magnetised. Then as there are tides in the sea around us and probably in the earth's crust, so there are certainly very large tides in the ocean of air above us: and may not the sun and moon, by dragging this air towards them as the earth revolves, cause that friction between air and earth, and also that evaporation, which together may account for the presence of, and keep up the supply of, positive electricity in the air and negative electricity in the earth? Again, these tides in the atmosphere will cause the mass of it to lag behind the revolving solid earth, and at a height of thirty or forty miles we have a layer of air which, for air, is a comparatively good conductor of electricity. Here then we have not a lagging of the magnet behind the conductor, but a lagging of the conductor behind the magnet, and hence, according to the laws of Faraday, we may expect a current or a gradual heaping up of electricity in the air in the opposite direction to the current in the earth's crust. Thus the regular tidal waves in the atmosphere would cause the gradual transfer of positive electricity from the poles towards the equator. This transfer may be of the nature of a current of electricity or of a mass of air carrying a static charge of electricity with it, for as Prof. Rowland has shown that the motion of a static charge will produce magnetism, so we may expect from the principles of conservation of electricity that a change in the position of a magnet will under such circumstances produce motion of the static charge of electricity. When the air becomes charged up to discharging point, then we may get the sudden discharges such as the aurora in the air and the earth current in the earth; and since the conducting layer of air approaches nearer to the earth in the colder polar regions, possibly within less than twenty miles of the earth's surface, it may be found that the discharge of the aurora may even take place from earth to air by gradual slow discharge, aided as it may be by the state of moisture of the air and by change of temperature and other causes.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—W. H. Caldwell, B.A., of Caius College, has been nominated to study at the Zoological Station at Naples.

Mr. F. M. Balfour, F.R.S., has been elected President of the Cambridge Philosophical Society. Prof. Newton in laying down the office referred with pleasure to the removal and the change in the management of the Society's library. Since the transfer to the new room about 500 volumes have been presented to the library by Professors Humphry and Newton, Mr. J. W. Clark, Mr. F. M. Balfour, and Mr. Horace Darwin.

Open Scholarships for Natural Science have been offered by Trinity College (date of examination, March 22 next); subjects those of the Natural Science Tripos; by St. John's College, subjects, Chemistry, Physics, Physiology, with Geology, Comparative Anatomy, and Botany (the last three only if notice be given beforehand), date, March 22; by Caius College, date March 28, subjects, Chemistry, and either Biology or Physics; by Christ's, Emmanuel, and Sidney Sussex Colleges, at a common examination; subjects, Physics, Chemistry, Biology, and Geology; date March 28.

UNIVERSITY COLLEGE, LIVERPOOL.—The Council of the College have appointed Dr. W. A. Herdman to the professorship of natural history, founded by Lord Derby in connection with University College. Dr. Herdman is a graduate of the University of Edinburgh. He took the degree of Bachelor of Science in 1879 in the department of Natural Science, and in the same year was intrusted by Sir Wyville Thomson with the preparation of the report on the collection of Tunicula obtained during the *Challenger* Expedition. The Council have also appointed Dr. J. Campbell Brown to the professorship of chemistry in the same college. Dr. Campbell Brown has for several years held the office of borough and county analyst, and of lecturer upon chemistry at the Royal Infirmary School of Medicine.

DR. ALEXANDER BAIN, lately Professor of Logic at Aberdeen, has been elected Lord Rector of that University.

SOCIETIES AND ACADEMIES

LONDON

Anthropological Institute, November 8.—Prof. W. H. Flower, F.R.S., vice-president, in the chair.—The following new Members were announced:—Miss Becker, Mrs. R. Crawshay, Mrs. Lloyd, Miss Mary Sheldon, Miss Eleanor E. Smith, Miss Wolfe, Prof. Acland, F.R.S., James Backhouse, William Bowman, F.R.S., Alfred T. Brett, M.D., Rev. H. Canham, John G. Garson, M.D., Hugh T. Hall, F.G.S., Capt. Hozier, W. J. Knowles, E. Llanfair Lewes, Alfred Lingard, M.B., G. D. Longstaff, M.D., William Parkin, H. Seebohm, F.L.S., Mark Stirrup, F.G.S., H. Stopes, F.G.S., Richard Thompson, Prof. E. Perceval Wright, F.L.S.; also Dr. Josef Majer of Cracow as a Corresponding Member.—Dr. J. G. Garson exhibited some improved forms of anthropometric instruments.—Mr. Everard

F. im Thurn read a paper on the animism of the Indians of British Guiana. After defining animism as belief in the existence of spirit in any form, the author stated that the animism of the Indians of Guiana, in common probably with that of many other American tribes, is not only of an exceedingly pure and rudimentary kind, but is much more primitive than has yet been recognised by students of religious evolution. The Indian belief is that each object and phenomenon of the visible world consists of body and spirit; and these countless dual beings differ from each other only in bodily form and in the degree of brute force or cunning which they possess, but are none of them distinguished by the possession of any sort of divine character. There is no belief, of genuine Indian origin, in gods or a God, in heaven or hell, or in reward or punishment after death; nor is any form of worship practised. The author also indicated how in this belief may be found the germs from which all the features of the higher religions have arisen by modification.

PARIS

Academy of Sciences, November 7.—M. Wurtz in the chair.—The following papers were read: -On the limits of electrolysis, by M. Berthelot. In the electrolysis of sulphate of potash (as also of haloid salts), the smallest sum of energies capable of working the decomposition is far below that which would be required for the previous setting at liberty of the alkaline metal. It is equivalent to the separation of the acid and the base, plus either the separation of the oxygen and the metal at expense of the base, or the decomposition of the acidulated water.—On the combustions effected by bioxide of nitrogen, by M. Berthelot. The property of burning at expense of bioxide of nitrogen under influence of a flame or electric spark, depends mainly (the author shows) on the temperature developed. Of the mixtures tabulated, none that develop a temperature theoretically under 7000° are inflamed; while those developing a higher temperature burn or detonate.—Synthetic experiments in artificial reproduction of meteorites, by MM. Fouqué and Lévy. By igneous fusion they have obtained bodies closely resembling some oligosideric meteorites; one type containing felspathic products, and another not. The former contains anorthite associated with pyroxyene and enstatite (eukrite) or peridote (howardite); the latter peridote, enstatite, oxydulated iron, and a pyroxene exclusively magnesian.—Solution of two questions of maritime hydraulics, by M. Cialdi. One refers to the force governing the sand of banks and harbours; (Cialdi's theory that the undulatory motion is the prime force is now accepted, as against that which puts the littoral current first). The other refers to the method of construction of moles for harbours by the Romans; (they did not make these with apertures where there was exposure to the open sea).—On the comparison of the waters of the Isère and those of the Durance in their hydrographic and agronomic relations, by M. de Gasparin. He controverts some views of M. Dumont.—Report on a memoir of M. Leauté on teledynamic transmissions. The author's solution of the problem is pronounced complete, theoretically and practically.—On silica and silicates of lithine, by MM. Hautefeuille and Margottet. *Inter alia*, three new crystallised silicates of lithine have been obtained (by means of chloride of lithium in fusion), and it is proved that silica may take the form of quartz in presence of a fused chloride.—On the means to employ for destroying the winter-egg of phylloxera, by M. Mayet. He considers it best to operate where the vines have every year galls on the leaves, and to treat (with insecticide) only the wood of two or three years.—A work by M. du Bocage (Lisbon) on the "Ornithology of Angola" was presented.—Elements of Denning's comet (1881 *f*), by M. Schulhof.—On a general formula for development of the principal part of the perturbative function, by M. Baillaud.—On the reduction of Abelian integrals, by M. Picard.—On linear differential equations, the integrals of which verify relations of the form $F[\phi(x)] = \psi(x)F(x)$, by M. Appell —On the integration of an equation with partial derivatives of the second order, by M. Teixeira.—Mode of transmission, in an isotropic solid (in equilibrium) of the pressure exerted on a very small part of its surface, by M. Boussinesq.—On the possibility of electric equilibrium, by M. Lévy.—On the product and the limit of operation of the transport of force by electricity, by M. Lévy.—Articulated systems, giving rectilinear motion or circular curvature, by Prince Gazarine.—Experimental method of determination of the ohm, by M. Lippmann.—Action of cold on the voltaic arc, by M. Tommasi. He used as rheophores, copper U-tubes (placed *vis-à-vis* horizontally), through which ran cold water. The luminous power is considerably weakened; the arc is very unstable; it does not ignite paper held 0·004m. above it; it is very mobile, and its form is like that of a drop of liquid in the spheroidal state; it is attracted and put out by a magnet; and there seemed to be more ozone than when the arc is not cooled. The flame was slightly green.—On an electric method for determining, with a needle, the position and depth of a projectile, or other metallic substance, in the human body, by Prof. Bell. A fine needle, connected by wire with a telephone, is inserted; and a metallic plate, similarly connected, is applied to the skin. A sound is heard when the ball is reached. A trembler may be introduced into the circuit giving a musical note in the telephone on contact of needle and ball; a battery may also be included.—New demonstration of Riemann's theorem, by M. Croullebois.—The direct-vision spectroscope with calcareous spar, by M. Zenger. He combines a single prism of spar of 75° refringent angle, with a fluid prism (sulphide of carbon, oil of cassia, or other liquid) of the same angle. The dispersion is very great. The red image of the protuberances can be obtained with great intensity, there being small loss by absorption and none by reflection.—On the function which expresses the gaseous state, by M. Gouilly.—On cuproso-cupric sulphite, by M. Etard.—On a hydrate of chromic bromide, by M. Varenne.—Action of hydracids on alkaline chromates, by M. Varenne.—Reply to M. Debray on dissociation of sulphydrates of ammonia, by MM. Engel and Moitessier.—On the vapour-tensions of carbamate of ammonia, by M. Isambert.—Modifications of composition of green fodder kept *en silo*, by M. Lechantier. Maize and trefoil lost a little of their azotised matter, but the loss of glucosides was much greater; the chief loss being now in the glucose and sugar group, now in the starch and cellulose. Fatty matter increased.—Artificial peridote produced in presence of steam, at ordinary pressure, by M. Meunier.—Action of hydriodic acid on chloroiodide of propylene and on chloride of isopropyl, by M. Silva.—On the contagion of tuberculosis, by M. Toussaint. *Inter alia*, tuberculosis becomes more powerful and rapid in its action the oftener it is inoculated.—On the physiological action of codethyline, by M. Bochefontaine. This action seems to consist in an exaltation of the reflex properties of the grey substance of the bulbo-medullary nerve-centres.—Contribution to a study of Flagellata, by M. Kunstler. He has found an organism very like noctiluca, but living in fresh water.—Observations on rotators of the genus *Melicerta*, by M. Joliet.—On the vitality of germs of *Artemia salina* and *Blepharisma lateritia*, by M. Certes.—On the winter spores of *Peronospora viticola*, by M. Prillieux.—Discovery of gypsum in the strata of the superior Eocene formation of Peru, by M. Caraven-Cachin.—On the characters of speech in deaf-mutes taught to articulate, by M. Hément. He maintains that these persons have the accent of their country, indicating organic conformations similar to those of their parents. M. Blanchard disputed this.—On the spontaneous insensibility of the sensitive plant, by M. Musset. A sudden fall of temperature suspends spontaneous movements of the plant (as chloroform, &c., suspend provoked movements)

ANTI-VIVISECTION *versus* HUMANITY

THE physiology of the brain is a subject which has long been matter of much speculation and of some experiment, but till twelve years ago little was known about it. The experiments of Flourens and others had taught us something about the functions of the cerebellum, and Broca's observations on disease had led him to localise speech in the third left frontal convolution; but with these exceptions the functions of the different parts of the cerebrum were almost entirely unknown; although, as a whole, it was regarded as the organ of thought. The experiments of Fritsch and Hitzig, published in 1870, showed that the cortex of the brain could be excited by galvanic currents, although mechanical irritation seemed to have no effect upon it. When certain parts of the cortex were thus irritated in the dog, definite movements of the paws ensued.

In a series of experiments published in the West-Riding Asylum Reports for 1873, Dr. Ferrier confirmed these results, and greatly extended them by experimenting on guinea-pigs, rabbits, and cats, as well as by investigating more fully and precisely the various areas in the brain of the dog. Dr. Ferrier's most brilliant discoveries were due, however, to the happy thought of using monkeys as the subject of experiment. For though a general resemblance can be traced between the functions of different parts of the brain in rabbits or dogs, and in man, yet the brains of these animals are so little developed in comparison with that of man, that exact and definite conclusions regarding the human brain cannot be drawn from experiments on them. Monkeys resemble man more closely than quadrupeds in the more or less erect posture which they tend to assume, in the use of their hands and fingers as prehensile instruments, and even in their muscles of expression. Their brain, though less complicated than that of man, still corresponds closely with it in the general arrangement of the convolutions, and even in many details.

Dr. Ferrier's experiments were performed by anæsthetising the animal and removing a part of the skull so as to expose the brain. The animal was then allowed to recover either partially or completely from the anæsthetic. On the brain being stimulated by touching it with the wires of a battery at various points of its surface, definite movements resulted. A touch on one part, for example, would cause the animal to stretch out its paw as if to grasp some fruit, on another to raise its hand to its mouth, as if to convey the food into it, and another to move its mouth and tongue as if chewing. These motor areas were chiefly around the fissure of Rolando, towards the anterior part of the brain. Stimulation of the posterior parts appeared to cause sensation (not pain), a touch on one part causing the animal to look round as if it saw something unusual, on another to prick up its ears as if it heard something, and on others to move the nostrils and mouth as if it perceived some unusual smell or taste. Destruction of the surface of the brain at the parts whose stimulation caused movement resulted in the impairment or loss of the power of executing the corresponding movement voluntarily, and where stimulation caused sensation the destruction of the part diminished or destroyed the corresponding sensation of hearing, sight, or touch.

These experiments might seem at first sight necessarily to involve the infliction of great pain, and some unthinking people have loudly cried out against what they call horrid cruelty, and have denounced the experiments in no measured terms; yet the fact is that the animals experimented on suffer very little pain, and probably a single sportsman in a day's pheasant-shooting inflicts more pain than Dr. Ferrier has done in the whole course of his researches. Every one will understand this who has seen a child hurt its finger and cry bitterly for a few minutes, and then run cheerily about as soon as the wound was bound up.

The painful part of Dr. Ferrier's experiments, viz. the exposure of the brain, was performed under anæsthetics, and when the animals were allowed to recover they exhibited no signs of pain. Stimulation of the surface of the brain, even on the sensory areas, does not seem to cause pain. The effect of stimulating the motor areas and thus causing movements of the limbs in monkeys, appears to be simply to excite their wonder and curiosity at the extraordinary circumstance of their limbs moving independently of their volition.

The localisation of function in the brain is of exceeding interest as a simple addition to our knowledge of the wondrous mechanism of the body, but it is also of very great use in practical medicine. By means of it we are able to say, with considerable certainty, that the lesions which give rise to particular groups of symptoms are situated at this or that point in the brain. Ferrier found, for example, that stimulating one part of the brain would cause movements of the hand, ending in clenching of the fist, and if the stimulation were continued for a long time other muscles were involved, until at last the animal fell into an epileptic fit. Previous to Ferrier's researches we were in the dark regarding the origin of epileptic fits in man, but now when we find a fit beginning with clenching of the fist we can with considerable certainty localise the cause of it in a definite region of the brain. Not unfrequently epilepsy comes on after a blow or fall on the head, and may continue for months or years, completely ruining the patient's prospects, and perhaps ultimately destroying his intellect. In such cases the disease has been cured by the removal of the injured portion of skull; but before the researches of which we have been speaking showed how to localise the injury, this was impossible, except immediately after its inflection, and while the evidences of its position were unmistakable. Now, however, thanks to Dr. Ferrier, it is possible to operate successfully long after the injury, as the following case, which we extract from the *British Medical Journal*, will show:—

"A child, aged seven, received a blow from a poker; it produced no external wound, and no scar or depression of bone remained. A year later the child had an epileptic fit, and continued to have fits daily for about seven years, with occasional periods of exacerbation, at which time the fits increased to twenty or thirty a day. At the end of this time Dr. Ferrier was asked to see the child in consultation; tenderness was found over the right parietal region, with loss of power in the left hand and indistinct utterance from loss of muscular power in the lips. Trephining was decided upon, and Dr. Ferrier pointed out that the seat

for trephining should be rather low down, to correspond to the centres for the arm and lips, which seemed affected. This was done; for eight weeks after the operation the child was free from fits, and at the periodical exacerbation the fits returned with always diminishing severity."

We have given only one instance, but Dr. Echeverria has collected 165 cases of traumatic epilepsy, of which 64 per cent. were cured by trephining. Nor is it only in epilepsy that operative procedure, directed by the knowledge gained from Dr. Ferrier's researches, is useful. In abscess of the brain it guides the surgeon's knife to the spot where the pus has accumulated, and even when disease is due to tumours, it indicates their site, and enables them to be removed and the patient cured, as in a case reported in the *Glasgow Medical Journal*. It opens a new region in the treatment of diseases of the brain, of which it is impossible at present to see the limits; and when we consider how recently the discoveries have been made it seems extraordinary that they should have already been productive of so much benefit. Operations on the head are not however to be rashly undertaken, and in Dr. Ferrier's first experiments he found that injury to the brain was apt to spread beyond the primary limits of the lesion. Prof. Yeo therefore commenced a series of experiments for the purpose of discovering how far improved methods of operating would obviate the risk incurred in such operations, and his attempts have been very successful. These operations were carried out with a proper licence and certificate under the Vivisection Act. Dr. Ferrier embraced the opportunity of observing these animals, and aided Prof. Yeo by his advice, so that each experiment was utilised for the purpose of increasing our knowledge of localisation, and thus aiding diagnosis, as well as of improving the mode of treatment. For these observations he was summoned before the police-court last week by the Society for the Protection of Animals from Vivisection, on what grounds it is difficult to see. Though the summons was dismissed by the magistrate, the prosecution no doubt caused much worry to Dr. Ferrier, and might have caused expense, were it not that the British Medical Association took up and defended the case, in order to show its appreciation of the value of Dr. Ferrier's services both to medical science and suffering humanity. It is now about five years since the Vivisection Act was passed, and the late prosecution of Dr. Ferrier, while it shows how carefully the Act has been observed by physiologists, affords evidence that an Act which purported to be for the prevention of the abuse, is being converted into an instrument of annoyance to those who are best qualified for the use of experiments on animals. At the time the Act was passed many persons objected to it, on the ground that it was quite exceptional to legislate against an abuse which had never been proved to exist in this country. It has been shown by many statements made in the medical journals within the last few months that the Act is being administered in such a manner as seriously to interfere with the progress of science; and it seems not unlikely that the present insult to one of their number may rouse the medical profession to combined agitation against restraints on research for the acquisition of that knowledge which may enable them to lessen the sufferings or save the lives of their patients.

EGYPT OF THE PAST

The Egypt of the Past. By Erasmus Wilson, F.R.S. (London: Kegan Paul, Trench, and Co., 1881.)

THE increased interest taken in Ancient Egypt has produced of late two new histories in English, and two in French and German. The English histories are last in the field, and are those of Prof. Rawlinson and Sir Erasmus Wilson. These histories are not really the work of Egyptologists or experts like that of Brugsch Pacha and M. Maspero, but are attempts to produce readable works for popular purposes by writers interested in Egypt or writers of history, and have consequently all the merits and defects of that kind of way of treating the subject.

The present article is devoted to a consideration of the work of Prof. Wilson, which has last appeared, and is exclusively devoted to history. It comprises the history from the oldest days, the first appearance of the primitive Egyptian, the aboriginal of the Nile, till the last of the Pharaohs, the miserable Nectanebo, who abandoned his country, but not his wealth, to the foreigner B.C. 345, and from that time till to-day a foreigner, in accordance with the law of monarchical nations, has ruled the country with the usual results.

The question of the first man of the Nile has not yet been settled, and he was probably one of those types which have disappeared from view altogether, and belongs to the fossilised remains of the planet. But history has little to seek about the prehistoric races and evidence of an antecedent state of dawning civilisation; flint weapons are very scanty and obscure, and do not aid the solution of the problem The obscure period of "the followers of Horus" has no historical or chronological importance, and belongs to the hazy epoch known as mythical and immeasurable. Actual history, but not positive chronology, begins with Menes, and the facts ascribed to Menes are, according to historical criticism, such as can be accepted as credible.

It has been agreed to designate as the Old Empire that part of Egyptian history which glides from the first to the sixth dynasty. This comprises the Pyramid-builders, most, if not all, of whose geometric sepulchres are situated in the plains of Memphis and its vicinity on the western bank of the Nile. Although no pyramid can be identified with any king of the first dynasty, and the names of monarchs are known only from official lists and after-recollections, a monument of the second dynasty from a private tomb is in the Ashmolean Museum at Oxford, and shows that the civilisation at that remote period had attained the same excellence as at the fourth. It was under this dynasty that the worship of animals—an African idea—arose, and if the pyramid of Sakkarah, with its numerous chambers, was, as supposed, an early sepulchre of the Apis, that edifice must have been erected under the second dynasty, with all its geometric regularity and architectural knowledge, four centuries after Menes. Certainly writing, sculpture, painting, the arts and sciences had attained a great advancement and development. Still further advancement is visible under the third dynasty, and in the tombs which lie around the Pyramid at Meidoom sculpture had then reached a high excellence, and the portrait of the individual as well executed as the

Roman sculptor could produce it. The men were painted a kind of copper colour, the women yellow, like the Semitic races. The red tint appears later, and the lips at all periods seem to show that an infusion of black blood even at the earliest age had been transfused into the Egyptian race. Senefru or Senophris had already conquered the Arabian Peninsula of Mount Sinai and worked the turquoise mines of the Wady Magarah. Besides turquoise, however, copper slag has been found at the spot, but the *mafk*, an obscure word, sometimes apparently used for a light blue colour, is decidedly not copper. The Great Pyramids, however, are the work of the subsequent dynasty, whose history is chiefly an account of Pyramids and their construction, with an occasional notice of their builders, and the present work judiciously gives the history without the fallacious theories which have found favour with credulous enthusiasts.

Although iron weapons have not been found of the age of Cheops, a sheet of this metal was discovered in one of the air-passages, and a copper tool in another, and the name of one of the monarchs, Merba, "lover of metal," or "iron," occurs amongst the kings of the first dynasty. Except for monumental remains the history of the fourth dynasty is unimportant, although it kept up the conquests and mines of the Wady Magarah, and architecture and technical arts improved, while sculpture and portraiture continued their unrivalled career. With the fifth dynasty the interest begins to thicken, the Pyramids are no longer dumb stones unable to explain their appearances on the great Memphite plains. The presence of pyramids and obelisks had shown that there was a religious system; the inscriptions in the Pyramid of Phiops at Sakkarah, and those of his successor, show that the myth of Osiris and the cosmogonic ideas connected with it had already developed, while the passage of the soul along the starry heavens, and the constellations, especially Orion and the dog-star, prove that the eschatological notions of the period differed exceedingly from those of subsequent periods, while the ethical writers of the period herald the advent of philosophy. The sixth dynasty, the inscriptions on the pyramids of which have been recently discovered, follow the same ideas as the fifth dynasty. Sir Erasmus Wilson has now been able to avail himself of these recent discoveries of the texts of the tombs. After the sixth dynasty lists perhaps supply the succession, but there is a monumental gap till the eleventh, and thence from the twelfth—a fair succession. Thebes, Tanis, and Heliopolis supplant Memphis.

The fifth dynasty had no very important history, and that of the sixth only acquires importance from its enrolling negro troops for the purpose of its northern wars, and the religious inscriptions recently discovered in its Pyramids throw light not only on the earlier religion, but on the antiquity of the worship of the gods and their relative place in the religious system. The first dynasty after the sixth which has any history is undoubtedly the twelfth, although the tenth attempted to reach Punt or Somali, or Cape Guardafui—early evidence no doubt of sea-going ships on the Red Sea and eastern coast of Africa. The history of the twelfth dynasty, its obelisks, labyrinth, Lake Moeris, is well and fairly given, but no additional light is thrown on the period already well known from the monuments and the Turin Canon, and the Sallier and Berlin papyri. On the north this dynasty did not penetrate farther than the peninsula of Mount Sinai, transferring their search for turquoises and metals from the Wady Magarah to the Sarabout El Khadem in the vicinity. Distinguished as it is by the advance in the arts and sciences as manifested in the tombs of Memphis, Abydos, and Eileithyia, its principal features were the undying thirst for gold, and constant search for slaves in the South amongst the Negroes, and its fortifications over the South and North against Negroes and Asiatics. There is a fair account of the twelfth dynasty, but the history of that period is capable of some expansion. The obscure subsequent dynasties, especially the Shepherd rulers, various monuments and statues of whom have been found at Tanis, and are described in the writings of De Rougé and Mariette, are fairly given. Some further information might perhaps have been added, but there is enough to satisfy the lambent curiosity of the general reader. The history of the eighteenth dynasty is well known, and although the rich discovery of mummies at the Deir-el-Bahari has not added one iota to this period, it has confirmed some old ideas. It is certain that the queen of Aahmes I., called Aahmes Nefertari, "the good companion of Aahmes," was unequivocally black, and no sacred office could possibly wash that Æthiopian white. Black she was always painted, and an Erastian priesthood never attempted to whiten her face. The throne of Egypt under this dynasty was occupied not by one, but by a succession of mulattos, and there was no deficiency either of courage or intelligence in the monarchs who raised Egypt to the highest pitch of glory, and stretched the boundaries to the Euphrates, if not to India itself. Egypt, in fact, always had a great infusion of Nigritic blood in its population, more Semitic perhaps on the East and European on the West, but undoubtedly very Nigritic on the South, where the misegenation with the black races prevailed. The princes of Æthiopia, scions of the royal family, were no doubt at this time red Egyptians in their parentage; but there were then, as now, two kinds of Negroes, the black and the copper-coloured. Many of the male contemporaries of Cheops have a chocolate hue, which hardly agrees with a Caucasian origin. Sir Erasmus Wilson seems puzzled about the inscription at the base of the obelisk of Hatasu at Karnak; it did not dovetail in with chronological theories, so Lepsius assigned it to the "blundering stonecutter"; but later explanations solved the seven months, by showing that the kings dated their regnal years from their accession, and that the date of the accession fell within the seven months, and the seven months were in two regnal years, and that it was unnecessary to add twelve months to the calculation. This has been generally accepted by scrupulous chronologists only too anxious to play at figures, and it appears a natural one. No one need marvel at the rapidity of the work, as the wishes of tyrannical princes have always been carried out with a marvellous rapidity, without the least consideration for human life, much less of toil. The grandeur of the works of Thothmes III. at Karnak, his obelisks and his exploits, are given, but the ingenious capture of Joppa by a stratagem worthy of the pen of Polyænus, and the countries where Thothmes hunted the elephant, are not pointed out. India has been suggested,

and nearer than India on his eastern frontier he could not have found herds of this animal, while the Rutennu, a very Indo-Chinese looking race, brought as tribute to Egypt, in the reign of the great conqueror, the *white* elephant, painted red and white, with gilded ears and toes. Had the fame and terror of the Egyptian conqueror reached the confines of Burmah, and the princes of Indo-China propitiated the Egyptians with that expensive present, a white elephant. All this occurred about 1600 B.C., and eight centuries later, in the reign of Shalman er II., the elephant, as a rare animal, figures on the obelisk found at Nimroud depicted in a style far inferior to the Egyptian. The mutilated mummy of Thothmes has been found at the Deir-el-Bahari, and all that remains is inadequate to give an idea of his person. His successors came into conflict with the Khita, the supposed Hittites, but so did the Ptolemies long after the Hittite kingdom is supposed to have been extinguished. The account of the Pharaoh Khuenaten and the obscurity which prevails about the succession after that heretic, might have been enlarged, and a little more said about the Pharaoh Horus and the historical difficulties about his reign. The hypothesis of Brugsch Pacha, that he reigned twenty-one years, is plausible to superficial observation, but not acceptable on deeper reflection; but these are Egyptological points not in the absolute province of an historian, unless on separate independent philological research. The theory of Brugsch Pacha, that the invasion of Egypt by the Libyans was accompanied, not by Greeks and the people of the Isles, but by Colchian tribes from the Caucasus, although supported by ingenious philological reasons, is not accepted by Ebers and others, and is not entertained in the work. This account of the nineteenth dynasty and the route of the Exodus, it has been already pointed out, does not correspond with the physical conditions of the country or the late surveys, but then the original error is due to the French engineer whose hypothesis was too hastily seized on and proved with too much special pleading. The history of the twenty-first dynasty is only imperfectly known, but here the recent discoveries have thrown additional light on this obscure period. The mummies at the Deir-el-Bahari have aided in the determination of the succession, and it is evident that these high priests were not only descended from the Princes of Æthiopia, who, originally appointed by the Pharaohs, maintained a kind of hereditary succession, but also belonged to the black races, the flesh of Pinotem II. being unusually brown, and revealing a Nigritic descent, there was a strange similarity with the features of Khuenaten, who also probably appertained to the same race. The hypothesis that Shishak was an Assyrian king or prince is not confirmed by the annals of Assyria nor Nimroud, whose Egyptian name Namruth is supposed to have the meaning in the Æthiopian dialect of Panther. But the name of Nimroud is not yet identified either in the Assyrian or Babylonian, and although the names of Assyrian persons mentioned in Egyptian have little resemblance with those given by the Assyrians themselves, still ingenuity might convert Pul Ashar-nes into Assur-Nazir-Pal, who ruled some time about the period. The Æthiopian dynasty is given with some detail, but there is some difficulty about the Æthiopian Piankhi, who conquered the supposed dodekaroty or rulers, who presided over Egypt according to the Assyrian annals, and whose names are recorded on the historical cylinders of Assurbanihabla, or Assur-banipal, and enter into Egyptian history. The position of Piankhi is placed immediately before the twenty-sixth dynasty, on account of his having for antagonist Tefnekht or Tnephakhthus, the father of Bokkoris, king of the twenty-fourth line. But Piankhi's name occurs amongst the kings of the twenty-first dynasty, and Piankhi may have been placed too low in the series. The Æthiopian invasion of Egypt is amply detailed in the Assyrian annals, but the information of the Egyptian monuments about Sabaco and Tirhakah is scanty.

The "Egypt of the Past" may be safely commended to the general reader as containing in a lucid form all the contributions of monumental sources to Egyptian history; it is not too long nor detailed, and is in a portable form. The plates are very well executed, especially the woodcuts; the coloured lithographic ones are gaudy and hazy in the style of Turner, but as that is supposed to represent a kind of aërial perspective of the highest order, it will no doubt commend itself to æsthetic minds. It is, however, a good work, and well got up.

OUR BOOK SHELF

Natural Philosophy for London University Matriculation. By Edward B. Aveling, D.Sc. (London: Stewart and Co., 1881.)

WITH text-books innumerable devised specially for their use, it would be remarkable if candidates for the London matriculation should fail in natural philosophy. That so large a proportion should fail in this subject, as is the case, must be due not to the quantity, but to the quality of their sources of instruction. What then must be said of a teacher who takes upon himself to venture on the scene with an inferior and trashy work in which all the worst blunders of the exploded text-books of a past date are reproduced? Although the writer of the book lying before us professes his indebtedness to the excellent manuals of Dr. Wormell and Mr. Philip Magnus, and to the invaluable assistance of his friend Mrs. Annie Besant, he cannot be congratulated on his success in following in the tracks of his predecessors. His book is, in fact, a cram-book of the worst and weakest type. The barest minimum of the subject divided into the inevitable Statics and Dynamics constitutes the programme; Optics and Heat being somehow thrown in along with Moving Bodies as divisions of the latter of these two branches.

Passing over the Introduction, we arrive at the heading "Definition and Divisions," where the serious business of teaching natural philosophy begins with the words: "From its earliest years a child is surrounded by a world of beauty and of mystery," and the author proceeds anon to advance grave arguments for the conclusion "force, then, is the cause of motion." After this it is not very surprising to read (p. 165) that as the "phrase 'change of velocity' is cumbersome, it is replaced by the exceedingly important word 'acceleration.'" And then, as if the author were not sure whether to give us too little or too much in his definitions, we are told in the very next sentence: "Acceleration is the change of velocity per unit of time *that occurs in a unit of time*"! That this is no mere *lapsus calami* is clear from the next page, where it is twice stated that acceleration is the "change of velocity per second *that occurs in one second.*" Yet the author expressly states that "variable acceleration is not within our

ken in this book." The Second Law of Motion is given in the imperfect Whewellian instead of the perfect Newtonian form, in which all the best treatises on dynamics have given it since the salutary return to Newtonian precision was inaugurated by Thomson and Tait. On p. 198 the author proposes to measure gravity on an Atwood's machine, with a falling mass of one centigramme. Did he ever try the experiment? On p. 241 the student is told that the Torricellian vacuum is to be found in the space left by the mercury at the top of a *thermometer*! Under the heading of Calorimeters (which instruments, by the way, are nowhere described) the novice is informed that "Joule established the fact that 772 pounds of mass falling through one foot give out a thermal unit"; from which it would appear that heat is the product of a mass into a length. Bad as this is, it is pardonable beside a passage in the introductory part of the book (p. 10), in which the reader is assured that a force generates heat at the point of its application when the point of application does not move forward. One grows weary of gathering from the rank crop of blunders; but a final example—the very last sentence of the book—shows the accuracy of our author's physical knowledge as displayed in his theory of dew. "A tarpaulin spread over the ground, or nature's tarpaulin of clouds, will *reflect* the *radiating rays* (sic) of heat, and under the tarpaulin or clouds dew is not deposited."

"Let me start," says Dr. Aveling (p. 6), "with two truisms—(1) That no book is worth reading that is not worth analysing; (2) that the ideas enunciated by a teacher, either by voice or pen, are not thoroughly the ideas of the learner until they have been expressed again in his own words. If, therefore, that which I am about to write is in any sense useful, it will be worth the while of the student to make analysis thereof." What if the student's analysis throw unexpected light on the first of these truisms? S. P. T.

Der Völkergedanke im Aufbau einer Wissenschaft vom Menschen, und seine Begründung auf ethnologische Sammlungen. (Berlin, 1881.)

Die Vorgeschichte der Ethnologie. (Berlin, 1881.)

THESE two pamphlets, by Prof. Adolf Bastian, are written to promote the doctrine he is never weary of teaching, that the scientific method of studying man is the museum-method of collecting and classifying his results, whether these be weapons or idols, or myths or superstitions, or what not. When in a group of such things there comes into view a common principle or thought, this is a *Volksgedanke*, a manifestation of the popular mind, a definite something for the science of man to occupy itself about. It was the desire to get at such general principles of human action that led the late Prof. Waitz to compile his Anthropology, and Prof. Bastian has gathered, in the many volumes he has published, an even vaster museum of human facts. In the first-named of the two publications above, the reader will find collections of evidence as to many of the problems which are now occupying the minds of anthropologists, such as the primitive relations of the sexes, the development of the family and of property, and the belief in ancestral and patron spirits. The few lines of comment with which the author links together his pages of citations are of especial value, as giving his judgment of the meaning of the facts. In the second pamphlet the author traces the growth of anthropological museums out of the old cabinets of curiosities. Neither treatise is well suited to quote passages from, as these lose their value when disconnected from the rest, like single specimens taken out of the museum. Now and then Prof. Bastian makes a sort of holiday digression, for instance where he collects page upon page about modern European miracles, relics, and pilgrimages, about which he truly says, "the nature-peoples, with their rude, clumsy fetishes, are no match for the subtleties of super-refined civilisation" E. B. T.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Telescopic Definition in a Hazy Sky

THE diminution of star disks during temporary haze or even by a thin passing cloud has been particularly noticed by Sir John Herschel. The effect of this haze is apparently to diminish the intensity of diffraction phenomena. The markings on the full moon have never been seen so blackened and distinct as through the haze of a London fog. On one occasion a very gentle east wind brought down a London fog to Reading. That evening the air was extremely still, but embrowned with the haze. Castor bore a magnifying power of 600 with a Wray $5\frac{1}{4}$ achromatic. The object-glass was being adjusted to the axis of the tube. Finally an intense jet black ring was seen to surround each star of this celebrated double, supplemented with one bright perfectly defined diffraction-ring, then a fainter ring at a further distance could be descried. The perfection of this definition has never since been attained. The haze had settled down into still air. The eastern breeze had died away. The brown fog remained in the sky; diffraction assumed its most perfect form. The moon bore any power I could muster with absolutely steady definition. These states of the atmosphere are extremely rare. I can now record a repetition of this wonderful steadiness. On November 9 Col. Abadie, Mr. Maunsel, and myself, were observing Saturn with an $8\frac{1}{2}$ Calver mirror. The crape veil and belts were well shown with the pale blue Polar cap. Ball's division was intensely black. The outer ring was narrow, and its dark grey tint contrasted strongly with the brilliant whiteness of the inner ring. I was greatly astonished, however, to descry Encke's division on the outer ring usually called A. The shadows of the ball were well marked. The eastward shadow much stronger than the western. A very brilliant narrow band edged the northern belt near the plane of the rings. The inner edge of the ring B projected a thin shadow on the ball. A lady who had no previous knowledge of the belts, entering the observatory last night, said they appeared to consist of several fine lines of parallel bands separated by very fine brighter bands. At 11 p.m. there was a very wide narrow halo round the moon. Saturn appeared much bedimmed, and Jupiter shorn of his brilliance. Yet Col. Abadie writes: "Jupiter was a sight to be remembered. The distinctness of all the belts was enhanced by bright zones; one to the north of the uppermost belt was particularly to be noticed. The clouds between the equatorial belts changed in appearance from being very fleecy to a long wavy appearance" (we were observing about three hours). The moon was too dim for observation. Encke's division is so seldom seen in my experience, its appearance in the field of so small a telescope was a matter of great surprise; and but for the concurrent testimony of two others for about a space of three hours, I certainly should have greatly doubted the accuracy of the observation. At all events, it is a valuable demonstration of the value of the *chiaro-oscuro* in astronomical research.

Eastbourne, November 16 G. W. ROYSTON-PIGOTT

The Morteratsch Glacier

DURING my stay in the Engadine this summer I took the opportunity of making a few observations relative to the movement of the Morteratsch Glacier, which may be of interest to some of your readers. These observations were taken *inside* the artificial cave of the above glacier in preference to the surface, as I thereby obtained a more direct measurement with a fixed point, as will be shown presently, and greater protection for the provisionary stations, made in the ice, against disturbances of fluctuating temperatures or the curiosity of visitors. The arrangement was very simple, namely: in the roof of the cave 2—$\frac{3}{4}$ in. round staves 2 feet long were fixed, at a relative angle of 45°, in such a way, that they prevented each other from dropping out, and were further clamped together by a small metal band, from which a plumb-bob was

suspended. Below this, on the floor of the cave, was a boulder, firmly embedded in the earth, and unaffected by the ice; this constituted my fixed point, a line being cut on it to correspond with the centre of the bob. In this way any movement of the staves with the ice could easily be measured off. The following are some of the results obtained, and I would draw special attention to the fact that, although the valley narrows considerably towards the snout end of the glacier, and in consequence one would expect an increase in the flowing speed, the observations prove a decrease in speed to nearly one-third. Movement in cave from August 1 to September 18, or forty nine days, max. ·354 in., min. ·093 in., mean ·176 in. per day. (The surface movement taken at side of glacier, three-eighths of a mile from snout, up the valley, amounted to ·516 in. per day.) End of glacier receded in the same time 19 ft., or 4·65 in. per day. Ice advanced $8\frac{1}{4}$ in.; total loss in length 18 ft. $3\frac{3}{4}$ in., or nearly 4·5 in. per day. I must add that the point of observation was fixed at 40 ft. from the entrance, as beyond that and further in the cave the floor formed part of the glacier, and no fixed station could be found. Also, the surface friction of the ice on the shore—both at the side of the glacier, where the surface measurements were made, and at the cave—was considered about equal, and could therefore not account for the great difference of movement. HUGO LEUPOLD

November 10

Arctic Research

WITH reference to a letter in your number of this week (NATURE, vol. xxv. p. 53), in which it is stated that the Arctic shores trending north with a *western* aspect, are most encumbered with ice, and that those with an *eastern* aspect are most free from ice; I beg to suggest that, in order that your readers may not be misled on a point of geographical interest, you would do well to insert the following extract from the writings of Sir Edward Parry:—

"I will mention a circumstance which has particularly forced itself upon my notice in the course of our various attempts to penetrate through the ice in these regions; which is that the eastern coast of any portion of land, or what is the same thing, the western sides of seas or inlets, having a trending at all approaching to north and south, are, at a given season of the year, generally more encumbered with ice than the shores which have an opposite aspect. The four following may be adduced in illustration of this fact, and cannot but appear somewhat striking when considered in viewing a map which exhibits the relative position of the shores in question.

"It is well known that, in the extensive northern sea reaching from latitude 60° to 80°, bounded on the east by Lapland and Spitzbergen, and on the west by Greenland; the whole of the latter coast is blocked up by ice throughout the summer, so as to make it at least a matter of no easy enterprise to approach it, while the navigation of the eastern portion of that sea may be easily performed without difficulty, even to a very high latitude, and at an early part of the season. A second equally well-known instance occurs in the navigation of Davis Strait, which, from about Resolution Island, in latitude $61\frac{1}{2}$°, to the parallel of at least 70, is usually inaccessible as late as the month of August, and a great deal of it, in summer, is not accessible at all; while a broad and navigable channel is found open on the eastern side of the strait (that is, on the western coast of Greenland) many weeks before that time. We experienced a third and very striking example of this kind in coasting the eastern shore of Melville Peninsula in the years 1822 and 1823, the whole of that coast being so loaded with ice as to make the navigation extremely difficult and dangerous. Now, on the eastern side of Fox Channel, there is reason to believe, as well from the account of that navigation in 1631, and that of Baffin in 1615, as from our own observations, that there is little or no ice during the summer season. The last instance of the same kind which I shall mention is that of Prince Regent's Inlet, and of which the events of this voyage furnish too striking a proof, the ice appearing always to cling to the western shore in a very remarkable manner, while the opposite coast is comparatively free from it.

"These facts, when taken together, have long ago impressed me with the idea that there must exist in the Polar regions some general motion of the sea towards the west, causing the ice to set in that direction, when not impelled by contrary winds or local and occasional currents, until it butts against those shores which are actually found to be most encumbered by it."

I need only add that all subsequent observation has confirmed the accuracy of Sir Edward Parry's general rule; to which of course there are exceptions caused by the action of local currents and winds. CLEMENTS R. MARKHAM

21, Eccleston Square, November 19

Curious Formations of Ice

DURING a botanical expedition recently made to Gangotri Glacier I noticed, early on the morning of October 6, some very beautiful and curious formations of ice, which must have been formed during the previous night. It was freezing hard when I left my camp, after an early breakfast. The small pools beside the river were completely frozen over, and the smooth boulders of granite were coated with thick flakes of ice, which greatly increased the difficulty and danger of walking. Ascending a steep grassy slope (a favourite feeding-ground at this time of the year for barhal, or Himalayan sheep), I found the ground clothed over with small masses of pure white ice, very like mushrooms at a distance; I cannot give a better description of their general character than to liken them to a certain kind of thin, wafer-like cylindrical biscuit, which is sometimes eaten as an accompaniment of ices, only they were pure white and not cylindrical, but rather funnel-shaped, the larger opening being uppermost. In most cases there were two to four of these funnels, forming clusters round the lower portion of the stems of a species of Polygonum, which was abundant in this part of the valley, in an extremely dried-up condition. I should be glad to know if this curious kind of ice structure has been observed elsewhere.

Saharunpore, N.W.P., October 31 J. F. DUTHIE

Meteor

A MAGNIFICENT purple meteor was observed here on November 15, at 5h. 54m. p.m. G.M.T., by the Rev. A. Corti and one of the assistants of the Observatory. When first seen below β Aurigæ it was not very bright, but as it was passing through the constellation Lynx its brilliancy increased until it outshone Jupiter. Its shape was at first round, but, when it had passed near ϕ Ursæ, it burst into three pieces between γ and χ Ursæ, the largest of the three pieces being closely followed by the other two, which were as bright as first-magnitude stars. They all disappeared near η Ursæ, the total arc described being more than 70°. The meteor was visible for seven seconds, and left a long train, which soon disappeared. The velocity of the meteor decreased gradually as it approached its bursting point.

S. J. PERRY

Stonyhurst Observatory, Whalley, November 17

AT a quarter to five yesterday afternoon, when the sun had scarcely set and no star was visible, I and another inhabitant of this place saw a large blue meteor issue from a height of twenty degrees above the north-west horizon, and fall in a sharp curve for, say fifteen degrees, until it disappeared behind some woods. In falling it scattered large fragments behind it, but retained its nucleus, beside which Mars looked quite sickly. How vivid must the meteoric light have been! M. L. ROUSE

Sunnymead, Chislehurst Common, November 21

I OBSERVED a fine meteor last night at 1·3 a.m. It came into sight so closely in the neighbourhood of a brilliant white star, which I took to be Sirius, that, as it shot in an apparent straight line, or segment of a very large arc, across the sky, midway between Orion, then due south, and the horizon, the momentary illusion to the eye was that the star, which it equalled in magnitude and brilliancy had left its place and travelled west.

Bregner, Bournemouth, November 18 HENRY CECIL

ABOUT 5.45 on the evening of the 15th inst. a meteor, larger than Jupiter, but not so bright, appeared under Capella, and took a horizontal course, till it disappeared at about the same distance below the terminal star in the tail of Ursa Major. I never saw so long a flight. Twice in its course it disappeared or became very faint. Near the end it broke into two, the second part following the former. At any computation of its distance its flight in the upper regions of the atmosphere must have been in an enormously extended path. My son, who was with me, conjectured that its disappearance might be owing to its passing

through a deep trough, or hollow of a wave, in the surface of the atmospheric ocean; in which the diminution of the friction might occasion a loss of incandescence; a suggestion rather favoured by the repetition of the phenomenon. Perhaps the meteor was only making ducks and drakes.

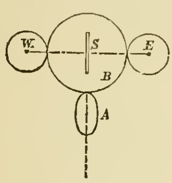
Rainhill, November 17 HENRY H. HIGGINS

Integrating Anemometer

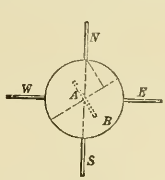
J'AI lu avec beaucoup d'intérêt la controverse suscitée dans les colonnes de votre estimable journal, à propos de "l'Anémomètre Intégrateur" présenté par M. Hele Shaw et le Dr. Wilson à la dernière réunion de "l'Association Britannique." Il arrive souvent, dans l'histoire des inventions, qu'une même idée, quoique diversement modifiée, vient presque simultanément à l'esprit de plusieurs individus travaillant dans des directions indépendentes, et il en résulte ainsi des questions de priorité difficiles à décider.

Ce n'est pas pour une question de ce genre que j'ose vous écrire aujourd'hui; mais l'idée de l'anémomètre intégrateur m'était venue aussi il y a quelques années, et la description de celui inventé par M. A. von Oettingen, que j'ai lu dans le "Repertorium" de M. Wild en juillet, 1878, me conduisit, si je n'ai pas mal compris, à la forme même de l'appareil de MM. Shaw et Wilson, et quelques jours plus tard à une autre, plus parfaite à mon avis, et que je n'ai pas encore eu l'occasion de mettre en pratique. C'est celle dont les organes les plus essentiels ont été représentés dans les figures ci-jointes.

Un disque (roller) vertical A peut, comme dans l'instrument de MM. Shaw et Wilson, prendre la même orientation que la girouette et au même temps tourner sur son axe horizontal avec une vîtesse proportionnelle à celle du vent. Sur ce disque s'appuit une sphère B, de poids et dimensions convenables, qui est aussi soutenu lateralement par quatre disques verticaux N., E., S., W., situés à angle droit entre eux. Le disque A fait mouvoir la sphère B dans le même plan vertical, et celle-ci les quatre disques lateraux; de sorte que, si les points de contact de ces disques avec la sphère ont lieu sur l'équateur dont le pôle est le point de contact du disque moteur, la vîtesse totale de celui-ci s'y trouvera decomposée dans les directions fondamentales N., S., E., W. Dès lors il suffira de munir chaque disque N., E.,



Projection verticale.



Projection horizontale.

S., W., ou bien deux disques quelconques adjacents, d'un compteur spécial, pour obtenir les composantes cardinales du vent.

Cet anémomètre intégrateur sera, comme ceux de MM. Shaw et Wilson et de M. Burton, plus simple que celui de M. von Oettingen, et en outre son action deviendra, pour ainsi dire, indéfinie, la transmission du mouvement s'y effectuant au moyen d'une sphère. Cette transmission se fait ici par *roulement sans glissement*, ce qui n'a pas lieu dans le système de M. von Oettingen, où cette circonstance constitue un grave défaut.

Pour ne pas prolonger trop cette lettre, je n'insisterai plus sur mon anémomètre, dont les indications peuvent être obtenues de diverses manières, et dont le mécanisme est susceptible de recevoir plusieurs applications.

Si vous croyez que les lignes précédentes contiennent quelqu'idée nouvelle et utile, je vous prie de vouloir bien les insérer dans votre estimable journal. En attendant je vous remercie d'avance, et veuillez aussi, Monsieur, agréer l'assurance de ma plus haute estimation. V. VENTOSA

Madrid, le 5 novembre

Geological Results of the Late Gales

THE late gales have had a very powerful effect in redistributing the beach-deposits along our coasts, and though many well-known geological sections have no doubt been covered up in consequence, many new ones have at the same time been brought to light. In this neighbourhood, for instance, at Whitley-by-the-Sea, near Tynemouth, a section of the highest interest to local geologists has been uncovered within the last few weeks, showing a well-marked uncomformity within the Coal-measures, which I, for one, although familiar with the place for years, was totally unaware of, and which, if ever observed before, has certainly never been recorded. For some time to come the section will probably remain exposed at low tides, as the sand which formerly concealed it has been entirely swept away. I will not weary your readers with a detailed description of the section, which will, in due time, be more appropriately published elsewhere, but merely beg to record the observation as an example of the kind of new matter that many geologists resident on or near our coasts will probably come across by searching along the cliff-bases just now. G. A. LEBOUR

November 15

The Recent Weather

AT 11 o'clock last night two thermometers outside stood at 66°·75. It was pitch dark, and blowing fresh from south-south-west. When last tested, these thermometers were not ·25 of a degree in error. Was such a temperature ever registered at such an hour on the 13th November before in Great Britain or Ireland? RICHARD M. BARRINGTON

Bray, Co. Wicklow, Ireland, November 14

Dipladenia amabilis

IF it is not already well known, it may interest some of your readers to hear that flowers of the *Dipladenia amabilis* last for a much longer time when placed in water if their tubes be also filled. Even when "too utterly weary" they can be revived in the manner I have mentioned. This may have reference to the fact that these flowers, unlike many creepers, generally turn upwards, and would therefore be likely to catch rainwater.

AMY MULHOLLAND

High Elms, Hayes, Kent, November 13

"The Lepidoptera of Ceylon"

WITH reference to the remarks of Dr. H. Trimen (vol. xxv. p. 32) to this work, now in course of publication under the patronage of the Ceylon Government, of which Parts I. and II. only had then reached him, and especially to the "protest" which he "feels bound to enter" against the name of the artist as there printed at the foot of the several plates, I may be allowed to state that the *original drawings* made by the native artist, Mr. W. de Alwis (representing about 350 species, or one-third only of the number of Ceylon Lepidoptera known to the author, and that will eventually be figured in this work), which Dr. Trimen states are in the Colombo Museum, were copied by his brother, Mr. George de Alwis, for Sir William H. Gregory, whilst Governor of the Island. These copies are in the author's hands, and it is from them, wherever a suitable figure is available, as well as from specimens of the actual species there represented, that the drawings, and afterwards the lithographing the figures on the stone, were made. The artist's name, as there printed on the several plates of the work, is consequently perfectly correct. In due course, Part IV.—completing vol. i. of this work—will reach Ceylon, wherein the preface is printed, and Dr. Trimen will there see that the native artist to whom he so specially refers, receives the necessary acknowledgment of his labours from the author. F. MOORE

Penge, S.E.

A GLIMPSE THROUGH THE CORRIDORS OF TIME [1]

I.

YOUR Committee has done me much honour by inviting me to deliver the first lecture in this large and very beautiful hall. In accepting the task I was aware that it involved a great responsibility, but I had various grounds of encouragement. I remembered that I was not coming among you as a stranger, and I knew that I had a subject worthy of a memorable occasion. I would I were

[1] Lecture delivered at the Midland Institute, Birmingham, on October 24, 1881, by Prof. Robert S. Ball, LL.D., F.R.S., Andrews Professor of Astronomy in the University of Dublin, and Royal Astronomer of Ireland. Contributed by the Author.

equally confident of my ability to do justice to so noble a theme.

The lecture bears the somewhat poetic title of "A Glimpse through the Corridors of Time." A poetic title has been chosen, because if I can properly exhibit the subject you will see that it appeals powerfully to the imagination as well as to the reason. I shall invite you to use your imagination to aid in looking back into the very remotest recesses of antiquity. And when I speak of antiquity I do not mean the paltry centuries with which our historians have to deal. The ancient days to which I refer are vastly anterior to those of the "grand old masters" and those of the "bards sublime." Nor do we even allude to the thousands of years which have elapsed since Babylon and Nineveh were splendid and populous cities Even the noble pyramids of Egypt are but of yesterday when compared with the æons of years which must pass before our review.

The most ancient human monuments that now exist cannot, I suppose, be more than a few thousand years old. Five thousand years nearly exhausts all historical time. Ten thousand years certainly does. Though we have no earlier historical record, yet other records are not wanting. Geology tells us that ten thousand years is but a mere moment in the span of the earth's history. We learn from geology that even the career of man himself has lasted far more than ten thousand years. Yet man is but the latest addition to the succession of life on the earth. For the chronology of the earlier epochs of the earth's history we require majestic units to give adequate expression to our dates. Thousands of years are not sufficient, nor tens of thousands, nor hundreds of thousands. The course of geological time is to be reckoned in millions of years.

The corridors of time through which I wish to give you a glimpse are these dignified millions. Yet our retrospect will only extend to a certain definite epoch in the past history of our earth. We speak of nothing anterior to the time when our earth assumed the dignity of maternity, and brought forth its first and only child. We shall trace the development of that child which, though millions of years old, is still in dependence on its parent. We shall describe the influence of the parent over the child and the not less remarkable reaction of the child upon the parent. We shall foreshadow the destiny which still awaits the mother and child when millions of years shall have elapsed.

At the time of its birth the earth was not as we see it now, clothed with vegetation and teeming with animal life. It was a huge inorganic mass, too hot for life, perhaps hot enough to be soft or viscid, if not actually molten. The offspring was what might be expected from such a parent. It was also a rude inorganic mass. Time has wrought wondrous changes in both parent and child. Time has transformed the earth into an abode of organic life. It has transformed the earth's offspring into our silvery moon.

It will be my duty to sketch for you the manner in which these changes have been brought about. To a great extent we can do this with no hesitating steps, we are guided by a light which cannot deceive. It is the light of mathematical reasoning. These discoveries are of an astronomical character, but they have not been made by telescopes. They have been made by diligent labours of the most abstruse kind. The mathematical astronomer sits at his desk, and not in an observatory. He has in his hand a pen and not a telescope. Before him lies a sheet of paper and not the starry heavens. He is no doubt furnished with a few facts from observation. It is his province to interpret those facts, to inform them with life, and to infer the unknown from the known. It is thus discoveries are made which are the sublimest efforts of human genius.

The argument on which I invite you to follow me is founded on a very simple matter. Many of those present go every summer to the sea-side. Those who do so are well acquainted with the daily ebb and flow which we call the tides. Even the children with their spades and buckets know how the flowing tide will fill their moats dug in the sand and inundate their mimic castles. In the ebb and flow of the tide we have a mechanical engine of mighty power. I hope this evening to point out the wonderful effect which tides have had on the earth in times past, as well as the effect they will exercise in the future. It is the tides which are to reveal to us a glimpse through the Corridors of Time.

The cause of the ebb and flow of the tide has long ceased to be a mystery. In the earliest times it was noticed that the tides were connected with the moon. Pliny and Aristotle both refer to the alliance between the tides and the age of the moon. It is well known that the tides on our coasts sometimes rise to an unusual height. Those who dwell on low ground adjoining tidal rivers are painfully aware of this fact by the floods which are often produced. Such occurrences generally take place at the time of new moon or of full moon. At first quarter or last quarter the tides are even below the usual height. A fisherman who has to regulate his movements by the tides will know full well that at certain times the tides rise higher and fall lower than at other times. He brings his boat out on the falling tide, he brings it back on the rising tide, and when making the harbour after a night's fishing, it would be natural to hear him say "Oh, we shall run in easily this morning, there is a strong tide, the moon was full last night." Or if he had to cross a dangerous bank he would soon learn the difference between the spring tide and the neap. Fishermen are not much addicted to abstract reasoning. For many centuries, perhaps indeed for thousands of years, observant men might have known that the moon and the tides were connected. But they did not know any reason why this connection should exist. I daresay they did not even know whether the moon was the cause of the tides or the tides the cause of the moon.

Nor is it easy to explain the tides. We were all taught that the moon makes the tides. Yet I can imagine an objector to say, If the moon makes the tides, why does it give Bristol a splendid tide of 40 feet, while London is put off with only 18? The true answer is that the height of the tide is largely affected by local circumstances, by the outline of the coasts, by estuaries and channels. It is even affected to some extent by the wind. Into such details, however, I do not now enter: all I require is that you shall admit that the moon causes the tides, and that the tides cause currents. In some few places the currents caused by the tides are made to do useful work. A large reservoir is filled by the rising tide, and as the water enters it turns a water-wheel. On the ebbing tide the water flows out of the reservoir, and again gives motion to a water-wheel. There is here a source of power, but it is only in very exceptional circumstances that such a contrivance can be worked economically. Sir W. Thomson, in his address to Section A of the British Association at York, went into this question in its commercial aspect. At present, however, we may say that the power of the tides is as much wasted as is the power of Niagara. Perhaps when coal becomes more scarce, and when the means of distributing power by electricity are more developed, the tides and the great waterfalls will be utilised; but that day will not be reached while coal is only a few shillings a ton.

Though we have not yet put the tides into harness, yet tides are not idle. Work they will do, whether useful or not. In some places the tidal currents are scouring out river-channels; in others they are moving sandbanks. From a scientific point of view the work done by the tides is of unspeakable importance. To realise the importance, let us ask the question, Whence is this energy

derived with which the tides do their work? The answer seems a very obvious one. If the tides are caused by the moon, the energy they possess must also be derived from the moon. This looks plain enough, but unfortunately it is not true. Would it be true to assert that the finger of the rifleman which pulls the trigger supplies the energy with which the rifle bullet is animated? Of course it would not. The energy is derived from the explosion of the gunpowder, and the pulling of the trigger is merely the means by which that energy is liberated. In a somewhat similar manner the tidal wave produced by the moon is the means whereby a part of the energy stored in the earth is compelled to expend itself in work. I do not say this is an obvious result. Indeed it depends upon a refined dynamical theorem, which it would be impossible to enter into here.

But what do we mean by taking energy from the earth? Let me illustrate this by a comparison between the earth rotating on its axis and the fly-wheel of an engine. The fly-wheel is a sort of reservoir, into which the engine pours its power at each stroke of the piston. The various machines in the mill merely draw off the power from the store accumulated in the fly-wheel. The earth is like a gigantic fly-wheel detached from the engine, though still connected with the machines in the mill. In that mighty fly-wheel a stupendous quantity of energy is stored up, and a stupendous quantity of energy would be given out before that fly-wheel would come to rest. The earth's rotation is the reservoir from whence the tides draw the energy they require for doing work. Hence it is that though the tides are caused by the moon, yet whenever they require energy they draw on the supply ready to hand in the rotation of the earth.

The earth differs from the fly-wheel of the engine in a very important point. As the energy is withdrawn from the fly-wheel by the machines in the mill, so it is restored thereto by the power of the steam-engine, and the fly runs uniformly. But the earth is merely the fly-wheel without the engine. When the work done by the tides withdraws energy from the earth, that energy is never restored. It therefore follows that the energy of the earth's rotation must be decreasing, This leads to a consequence of the most wonderful importance. It tells us that the speed with which the earth rotates on its axis is diminishing. We can state the result in a manner which has the merits of simplicity and brevity.

"The tides are increasing the length of the day."

This statement is the text of the discourse which I am to give you this evening. From this simple fact the new and wondrous theory of tidal evolution is deduced. A great scientific theory is generally the outcome of many minds. To a certain extent this is true of the theory of tidal evolution. It was Prof. Helmholtz who first appealed to what tides had already done on the moon. It was Prof. Purser who took an important step in the analytical theory. It was Sir William Thomson's mathematical genius which laid the broad and deep foundations of the fabric. These are the pioneers in this splendid research. But they were only the pioneers. The great theory itself is chiefly the work of one man. You are all familiar with the name he bears. The discoverer of tidal evolution is Mr. G. H. Darwin, Fellow of Trinity College, Cambridge.

It would be impracticable for me now to go into the actual mathematical calculations. I shall rather endeavour to give you an outline of this theory, shorn of its technical symbols. I think this can be done even though we attempt to retain the accuracy of mathematical language. Nor would it be fair to throw on Mr. Darwin or the other mathematicians I have named the responsibility for all I am going to say. I must be myself responsible for the way in which those theories are set forth, as well as for some of the deductions made from them.

At present no doubt the effect of the tides in changing the length of the day is very small. A day now is not appreciably longer than a day a hundred years ago. Even in a thousand years the change in the length of the day is only a fraction of a second. But the importance arises from the fact that the change, slow though it is, lies always in one direction. The day is continually increasing. In millions of years the accumulated effect becomes not only appreciable but even of startling magnitude.

The change in the length of the day must involve a corresponding change in the motion of the moon. This is by no means obvious. It depends upon an elaborate mathematical theorem. I cannot attempt to prove this for you, but I think I can state the result so that it can be understood without the proof. If the moon acts on the earth and retards the rotation of the earth, so, conversely, does the earth react upon the moon. The earth is tormented by the moon, so it strives to drive away its persecutor. At present the moon revolves round the earth at a distance of about 240,000 miles. The reaction of the earth tends to increase that distance, and to force the moon to revolve in an orbit which is continually getting larger and larger.

Here then we have two remarkable consequences of the tides which are inseparably connected. Remember also that we are not enunciating any mere speculative doctrine. These results are the inevitable consequences of the tides. If the earth had no seas or oceans, no lakes or rivers; if it were an absolutely rigid solid throughout its entire mass; then these changes could not take place. The length of the day would never alter, and the distance of the moon would only fluctuate between narrow limits.

As thousands of years roll on, the length of the day increases second by second, and the distance of the moon increases mile by mile. These changes are never reversed. It is the old story of the perpetual dropping. As the perpetual dropping wears away the stone, so the perpetual action of the tides has sculptured out the earth and moon. Still the action of the tides continues. To-day is longer than yesterday; yesterday is longer than the day before. A million years ago the day probably contained some minutes less than our present day of twenty-four hours. Our retrospect does not halt here; we at once project our view back to an incredibly remote epoch which was a crisis in the history of our system.

Let me say at once that there is great uncertainty about the date of that crisis. It must have been at least 50,000,000 years ago. It may have been very much earlier. This crisis was the interesting occasion when the moon was born. I wish I could chronicle the event with perfect accuracy, but I cannot be sure of anything except that it was more than 50,000,000 years ago.

I do not admit that there is anything discreditable about this uncertainty. Do you not know that our historians, who have records and monuments to help them, are often in great confusion about dates? I am not going to find any fault with historians. They do their best to learn the truth; but I cannot help reminding you that they are often as much in the dark about centuries as the astronomers are about millions. Take, for example, the siege of Troy, which Homer has immortalised, and ask the historians to state the date of that event. Some say that the siege of Troy was 1184 B.C., others that it was 900 B.C.; both are equally uncertain. Schliemann says that he found the remains of the town burned down, but that no one knows who did it or when it was done. Others, again, say that there was never any siege of Troy at all.

A recent instance which has attracted great and deserved attention is Schliemann's discovery at Mycenæ of what he considers to have been the tomb of Agamemnon. The tomb certainly did contain the remains of some mighty man, if we may judge by the 100 lb. weight of

gold ornaments which were found there. Most people think that these tombs, whosever they were, date from at least 1000 B.C. On the other hand, some very high authorities regard the monuments as the tombs of northern invaders who came into Greece 500-600 A.D. Here then we have a range of some 1500 years for the date of the tombs, and no dates between these two are possible. I am sure I do not pretend to decide between them, or even to have an opinion on the subject; but I cannot help saying that in one respect the astronomers are better off than the historians. The historians cannot even agree whether Schliemann's gold ornaments are B.C. or A.D. Astronomers are, at all events, certain that the date of the moon's birth was before the present era.

At the critical epoch to which our retrospect extends, the length of the day was only a very few hours. I cannot tell you exactly how many hours. It seems, however, to have been more than two and less than four. If we call it three hours we shall not be far from the truth. Perhaps you may think that if we looked back to a still earlier epoch, the day would become still less and finally disappear altogether! This is however not the case. The day can never have been much less than three hours in the present order of things. Everybody knows that the earth is not a sphere, but that there is a protuberance at the equator, so that, as our school books tell us, the earth is shaped like an orange. It is well known that this protuberance is due to the rotation of the earth on its axis, by which the equatorial parts bulge out by centrifugal force. The quicker the earth rotates the greater is the protuberance. If, however, the rate of rotation exceeds a certain limit the equatorial portions of the earth could no longer cling together. The attraction which unites them would be overcome by centrifugal force, and a general break up would occur. It can be shown that the rotation of the earth when on the point of rupture corresponds to a length of the day somewhere about the critical value of three hours, which we have already adopted. It is therefore impossible for us to suppose a day much shorter than three hours. What occurred prior to this I do not here discuss.

Let us leave the earth for a few minutes, and examine the past history of the moon. We have seen the moon revolves around the earth in an ever-widening orbit, and consequently the moon must in ancient times have been nearer the earth than it is now. No doubt the change is slow. There is not much difference between the orbit of the moon a thousand years ago and the orbit in which the moon is now moving.

But when we rise to millions of years the difference becomes very appreciable. Thirty or forty millions of years ago the moon was much closer to the earth than it is at present; very possibly the moon was then only half its present distance. We must however look still earlier, to a certain epoch not less than fifty millions of years ago. At that epoch the moon must have been so close to the earth that the two bodies were almost touching. I daresay this striking result will come upon many with surprise when they hear it for the first time. It was, I know, with great surprise that I myself read of it not many months ago. But the evidence is unimpeachable, and it is indeed wonderful to see how such information has been gained by merely looking at the ripples of the tide.

Everybody knows that the moon revolves now around the earth in a period of twenty-seven days. The period depends upon the distance between the earth and the moon. The time and the distance are connected together by one of Kepler's celebrated laws, so that, as the distance shortens, so must the time of revolution shorten. In earlier times the month must have been shorter than our present month. Some millions of years ago the moon completed its journey in a week instead of taking twenty-eight days as at present. Looking back earlier still, we find the month has dwindled down to a day, then down to a few hours, until at that wondrous epoch when the moon was almost touching the earth, the moon spun round the earth once every three hours.

It would require the combined powers of a poet and a mathematician to pourtray the scene with becoming dignity. I have only promised to give you that glimpse along the Corridors of Time which I have myself been able to obtain. The scene is laid in the abyss of space; the time is more than 50,000,000 years ago; the *dramatis personæ* are the earth and the moon.

In those ancient times I see our earth to be a noble globe, as it is at present. Yet it is not partly covered with oceans and partly clothed with verdure. The primæval earth seems rather a fiery and half-molten mass, where no organic life can dwell. Instead of the atmosphere which we now have, I see a dense mass of vapours in which perhaps all the oceans of the earth are suspended as clouds. I see that the sun still rises and sets to give the succession of day and of night, but the day and the night together only amount to three hours instead of twenty-four. Almost touching the chaotic mass of the earth is another much smaller and equally chaotic body. Around the earth I see this small body rapidly rotating. The two revolve together as if they were bound by invisible bands. This smaller body is the moon. Such is the picture which I wish to present to you as a glimpse through the Corridors of Time.

I have hitherto refrained from introducing any merely speculative matters. If we can believe anything of mathematics, anything of dynamics, we must admit that the picture I have attempted to outline is a faithful portrait. The only uncertain elements are the date and the periodic time. I do however now propose to venture on one speculation in which Mr. Darwin has indulged. I propose to offer a suggestion as to how a small body came into this most remarkable position close by the earth, and how its motion was produced.

We have hitherto been guided by the unerring light of dynamics, but at this momentous epoch dynamics deserts us, and we have only probability to guide our faltering steps. One hint, however, dynamics does give. It reminds us that a rotation once in three hours is very close to the quickest rotation which the earth could have without falling to pieces. As the earth was thus predisposed to rupture, it is of extreme interest to observe that a cause tending to precipitate such a rupture was then ready to hand. It seems not unlikely that we are indebted to the sun as the occasion by which the moon was fractured off from the earth and assumed the dignity of an independent body. It must be remembered that the sun produces tides in the earth as well as the moon, but the solar tides are so small compared with the lunar tides, that we have hitherto been enabled to neglect them. There could however have been no lunar tides before the moon existed, and consequently in the early ages before the moon was detached the earth was disturbed by the solar tides, and by the solar tides alone.

The primæval earth thus rose and fell under the tidal action of the sun. Probably there were no oceans then on the earth; but tides do not require oceans, or even water, for their operation. The primitive tides were manifested as throbs in the actual body of the earth itself, which was then in a more or less fluid condition. Even at this moment bodily tides are disturbing the solid earth beneath our feet; but these tides are now so small as to be imperceptible when compared with the oceanic tides.

(*To be continued.*)

SOME "GUESSES AT TRUTH" OF THE EMPEROR KHANG-HI

KHANG-HI or Khang-hsi, one of the greatest of Chinese emperors, and indeed of Asiatic rulers, was born in 1653 and ascended the throne in 1661. For

sixty-one years he ruled his vast dominions with vigour and success. His biographers, the Jesuit missionaries, whom he treated with unusual consideration, represent him as a Chinese Admirable Crichton—man of letters, *savant*, philosopher, politician, philanthropist, and warrior. In his early years he showed the utmost ardour for study, and the love of learning continued with him until his death. When the Jesuits taught European astronomy he did not hesitate to place himself under them as a student. He has left-behind him works on most branches of human knowledge, extending over a hundred volumes. The fourth part contains his observations on natural history and physics. It was translated into French by Père Amiot, and partially published at Paris towards the end of the last century in the *Mémoires concernant les Chinois*, and is to be found in the fourth volume of that series. We here extract and summarise a few of the Imperial opinions. To use the words of the translator, "If our scholars find nothing to learn there, they will at least see that there is not so much ignorance amongst foreign nations as is generally believed." We follow the Emperor's language as far as possible.

Earthquakes.—Some years ago, when reading for instruction, as well as to foster my love of truth and reason, I had the curiosity to examine into the causes of earthquakes. One writer says that they come from air confined in the bowels of the earth, seeking to burst its prison and make an aperture for itself. An earthquake hardly ever extends more than ten leagues in area, although its effects may be felt over a hundred leagues. The manner in which a shock is felt on the surface depends on the nature of the ground through which it is transmitted. When the air [within the earth] is exhausted by a great shock there is no danger of another for some time; but a weak shock is almost always the prelude to another. In the dynastic history of Song it is stated that earthquakes are produced by the struggles of the *Yang*[1] against obstacles within the earth; while another work attributes them to the efforts made by the *Yang* and *Yin* to separate from each other. The countries north-west of China are very subject to earthquakes, ten years scarcely ever passing without one. The reason of this is that these districts contain vast sandy tracts where there is little rain, and the air within the earth is therefore keener and more vigorous. Earthquakes, on the other hand, which take place in countries adjoining the sea are less violent, for the earth is humid, and softens the air. People accustomed to the sea assert that there is no wind before an earthquake, and that at such times experienced pilots get as far off from the land as possible. This shows that the shocks are caused wholly by air.

Volcanoes.—An ancient writer states that a certain mountain in Yunnan was called the fire-mountain, because flames came from an opening in it. Some modern critics have accused this historian of lying; but volcanoes do certainly exist. They are mentioned in the records of the Song dynasty, and in other books. In the country of the Mongols flames are thrown up in many places. The fertility of the soil is much increased by these fires, for the people sow their grain near them, and reap a bountiful harvest in a few months.

Form of the Earth.—It seems evident from tradition and records that the North Pole has always remained in the same position. But what is the shape of the earth? Europeans, who are great travellers, say that it is round, and astronomy confirms this. One philosopher says that it is very old, and compares it to the yolk of an egg. How many things there are which we do not understand, but which will be known to future ages! We know the extent of our knowledge from ancient books, and so it will be with posterity from our books.

The Mariner's Compass.—The magnetic needle always declines a little. It cannot point directly to the south. This declination is uncertain, and does not depend always on the country. In the twenty-second year of my reign (1683) it declined three degrees at Peking, but only two and a half at present. The declination may be towards the east in one province, and towards the west in another. One of the Song letters says that this depends on the manner in which the needle is magnetised; but then why should the same needle vary in different years? Moreover, each compass should have its own declination, and there should be some which do not decline at all. Can it be that there is some accidental cause which is peculiar to each country? I believe Europeans say the needle turns towards the north; the ancients say that it is towards the south. Which is right? Neither party says why, and therefore no more is learned from one than from the other. However the ancients are the earliest recorders, and the more I see the more convinced I am that they understood the workings of nature.

[1] *Yang* and *Yin*, the dual powers which, united, Chinese philosophers regard as forming, directing, and modifying all things: the male and female principles.

Sound and Tones.—Nothing is apparently more simple than the theory of sound; but nothing is really more difficult or complicated. Sound conveys to the mind the developed ideas of others. The pleasure derived from music is half way between that felt at the art and the grosser voluptuousness of the senses. People possess ears without reflecting why, or what services they render and pleasures they procure. For myself, I have always been struck with the manner in which the tone of voice expresses the most varied emotions of the mind. It is not necessary to see the face, or even to hear the words spoken; the tone alone is sufficient to tell how the speaker is moved. It is with the voice as with beauty, the impressions made by it vary according to the person. There are people whose voices go straight to the heart, and are sufficient of themselves to inspire friendship or love. This fact, it is certain, is part of a theory of which we as yet know little. I have read many works on the theory of echoes. The ignorant account for them by fables, and the learned give rules I think the vibrations of two loud chords struck in unison should serve to explain the reason of echoes heard in valleys and from the walls of buildings.

The simpler the laws of nature and the more sublime, the farther they are from our comprehension; my own thoughts are most frequently those of doubt. I turn away from those who pretend to explain everything and wait for an explanation of the concord of the cords of the *king*[1] with the flute, the different sounds of a hundred instruments, and the numerous voices that find their way into the air, bearing to our ears an indefinable sense of harmony. Awaiting this I say to myself with the ancients, "That which is nearest us is most remote from our comprehension." My ignorance on these matters has never troubled me, because it is no obstacle to that great duty to flee the evil and do that which is good.

Climate.—The effect of climate on the inhabitants of a country as well as on its productions is very great. The men of the south are women compared with those of the north. Vigour of body imparts vigour of mind. When our court was in the south the increase of riches consequent on its sojourn there caused luxury, effeminacy, and a corruption of manners which almost changed the men into women, so enslaved and delicate did they become in this prosperity. Now that it is in the north, they have become firmer, more active, and more regular. Naturalists and astrologers are equally mistaken when they judge of the character, genius, inclinations, and customs of men according to climate and the stars. My Tartars are Tartars, as regards manner of life, as much in the southern provinces as in the north, and people from the south retain their habits when they come to the north. The history of each province exhibits *savants*, literary men, artists, warriors, and monsters alike. Man is man everywhere, and there is often as much difference between the people in one town as between those in provinces distant from each other. Leou-chi has truly said, "No climate tames the tiger, or gives courage to the rabbit."

Winds.—The proverb says that the wind which blows is the same a hundred leagues away, but the rain which falls is not the same ten leagues off. Why should this be? One can only reason on facts after knowing them, and I know that the statement respecting the wind is not always correct, for there have been different winds at the same time in the provinces of Pechili and Shantung, which adjoin each other. It seems to me that winds depend on the nature of a country. One writer says that they depend on the motions of the stars, and that therefore they never cease, although at one time they may be more violent than at another, according as they are more or less impelled towards the earth. Moreover, the change in the direction of the wind comes from the same cause. The air being confined between the earth and the higher spheres, escapes where it can; and possibly the difference between a high and a low wind may be explained in this way. Another ancient writer says that the quarter from which the winds come depends on the season, and that they pass directly from one cardinal point to another. All

[1] *King*, a sort of dulcimer made of glass or stone.

other winds are temporary and accidental. I have paid particular attention to this matter, and I find the usual wind in Peking is from the south-west, and that other winds do not continue for any length of time. From the *Y-king* it appears that was the same in the most ancient times. It is a fact, attested by the daily record of our observatory here, that the wind does not remain long in any of the four cardinal points, as asserted by the writer above mentioned. Whatever be the causes of the different directions of the wind, it is certain that there are local and temporary, as well as general and universal ones. These can only be discovered by a multitude of observations. Again, why is it that when the wind blows, ice melts first at the water's edge, unless it be that the wind has penetrated the water? A more singular fact still is that there are some winds which are only felt in deep water. The history of the Yuen dynasty affirms that people bathing have become icy cold from a wind of which they have become suddenly sensible.

Thermal Springs.—Nothing is truer than that mineral waters are very efficacious in curing several maladies. They are better for those past forty years of age than for younger persons. Hot baths enfeeble and exhaust the latter, because, the blood still possessing all its force, they cause fermentation and perspiration, which disorder and injure the constitution. At a more advanced age, on the other hand, they revivify the blood and clear the bones, nerves, and tissues of the body from the impurities which years bring in their train. Baths should not be taken for some time after eating, and one should be careful of exposure to the air after them. I mention this because everything affecting the health of mankind interests me. It is clear that the heat, smell, taste, and medicinal virtues of thermal springs are the effects of a mixture of foreign substances in the water. But what are these substances? In what quantity and proportion are they present? This has not been sufficiently examined. Whenever I meet a mineral spring on my journey I examine it by means of an alembic, and by the alum, sulphur, or metal found there I know its properties. In this respect we must not follow the ancients. They decided superficially by the taste, smell, or colour. I wish these waters were studied better, as then it would be known what diseases they were best suited to cure.

We have not space to give any more of the Emperor's observations. Those translated above are sufficient to show his love of knowledge, and his desire to benefit his subjects by utilising the results of research. Some of his remarks are almost epigrammatic, and with a few of them we will bring this article to a close.

"Lying is the first resource of ignorance; but what shall we do when we do not know the truth? Be silent."

"I love to admire the manner in which nature confounds our ideas of the greatness of human industry, and baffles all the resources of our penetration. How difficult it is to admire worthily! Is not a small insect, a blade of grass, more worthy of our admiration than any production of human hands?"

"We spoil children by our puerile cares for their health. We have, alas! too many wants; why should we increase them?"

"Heaven provides for the wants of men according to the places in which they live."

"I prefer to procure a new species of fruit or of grain for my subjects than to build a hundred porcelain towers."[1]

"Every one desires health and loves life, but no one practises temperance and frugality. They invent pleasant remedies which they imagine will cause them to digest. Eat little, and you will digest much."

"I attribute my good health to the fact that I drink nothing but water, which I distil myself."[2]

[1] For a description of the celebrated porcelain tower of Nanking, see Williams's "Middle Kingdom," vol. i. p. 82. It should be added that this remarkable work was destroyed during the occupation of the city by the Taipings, and it may be said of it now, *etiam pereunt ruinæ*.

[2] The absence of any system of drainage in Chinese cities should be remembered here.

ON THE EVOLUTION OF ANTLERS IN THE RUMINANTS

THE development of antlers in the Ruminants to which Sir John Lubbock alluded in his address to the British Association at York, confirms the truth of the doctrine of evolution in so clear a way that it is well worthy of being laid before the readers of NATURE, although I have already brought it in part before the Geological Society in 1877 (*Quart. Journ. Geol. Soc.* xxxiv. 419), and published it in outline three years later, in my work on "Early Man in Britain, and His Place in the Tertiary Period" The results of an inquiry to which I was led by a systematic study, extending over several years, of the more important collections of fossil mammalia in Britain, France, and Italy, may be summed up as follows:—

In the Middle Stage of the Meiocene the cervine antler consists merely of a simple forked crown (*Cervus dicroceros*), which increases in size in the Upper Meiocene, although it still remains small and erect, like that of the roe. In *Cervus Matheroni* it measures 11·4 inches, and throws off not more than four tynes, all small (Fig. 1).

The deer living in Auvergne in the succeeding or Pleiocene age present us with another stage in the history of antler development. There for the first time we see antlers of the axis and Rusa type larger and longer and more branching than any antlers were before, and possessing three or more well-developed tynes (Figs. 2, 3, 4, 5).

Deer of this type abounded in Pleiocene Europe, and I have examined their remains from the Red Crag of Norwich and of Suffolk, from various localities in Middle and Southern France, from Italy, and even from the little Island of Capri. They belong to the Oriental division of the Cervidæ, and their presence in Europe confirms the evidence of the flora brought forward by the Count de Saporta, that the Pleiocene climate of Middle Europe was warm. They have probably disappeared from Europe in consequence of the lowering of the temperature in the Pleistocene Age, while their descendants have found a congenial home in the warmer regions of Eastern Asia.

In the latest stage of the Pleiocene—the Upper Pleiocene of the Val d'Arno—the *Cervus dicranios* of Nesti (Fig. 6) presents us with antlers much smaller than those of the Irish elk, but so complicated as almost to defy description. This animal survived into the succeeding age, and is found in the pre-glacial forest bed of Norfolk, being described by Dr. Falconer under the name of Sedgwick's Deer (*C. Sedgwickii*).

The Irish elk, moose, stag, reindeer, and fallow deer appear in Europe in the Pleistocene age, all with highly complicated antlers in the adult, and the first possessing the largest antlers as yet known. Of these the Irish elk disappeared in the Prehistoric age after having lived in countless herds in Ireland, while the rest have lived on into our own times in Euro-Asia, and, with the exception of the last, also in North America.

From this survey it is obvious that the cervine antlers have increased in size and complexity from the Mid-Meiocene to the Pleiostocene age, and that their successive changes are analogous to those which are observed in the development of antlers in the living deer, which begin with a simple point and increase in number of tynes till their limit of growth be reached. In other words, the development of antlers indicated at successive and widely separated pages of the geological record is the same as that observed in the history of a single living species. It is also obvious that the progressive diminution of size and complexity in the antlers from the present time back into the early Tertiary age shows that we are approaching the zero of antler-development in the Mid-Meiocene age. I have been unable to meet with a trace of any antler-bearing ruminant in the Lower Meiocenes either of Europe or of the United States.

Nor are we left without direct evidence on this point. The discoveries in the Mid-Meiocene shale of Sansan in the South of France, published by Prof. Ed. Lartet in 1839 and 1851, and those made in New Mexico, Colorado, and Nebraska, and published by Prof. Cope in 1874–1877, present us with a series of antlers in which the burr is conspicuous by its absence. Still more

recently, in 1878, similar specimens (*Procervulus*) have been described by Prof. Gaudry ("Les Enchainements," p. 87) from the Mid-Meiocene strata of Thenay in the valley of the Loire. In all these cases the bony prolongation of the frontals—for antler it can hardly be termed—is small, erect, and variously branched, is persistent through life, and probably, as Prof. Cope suggests, was covered, as in the giraffe, and on young growing antlers, with skin.

In some, however, of Prof. Cope's specimens a well-marked burr is to be seen on some of the tynes (The United States Geogr. Survey, Part II. vol. iv. Palæontology, Pl. lxxx., 3*b*, 4*a*), due perhaps to an accidental stripping of the velvet, and consequent inflammation, resulting

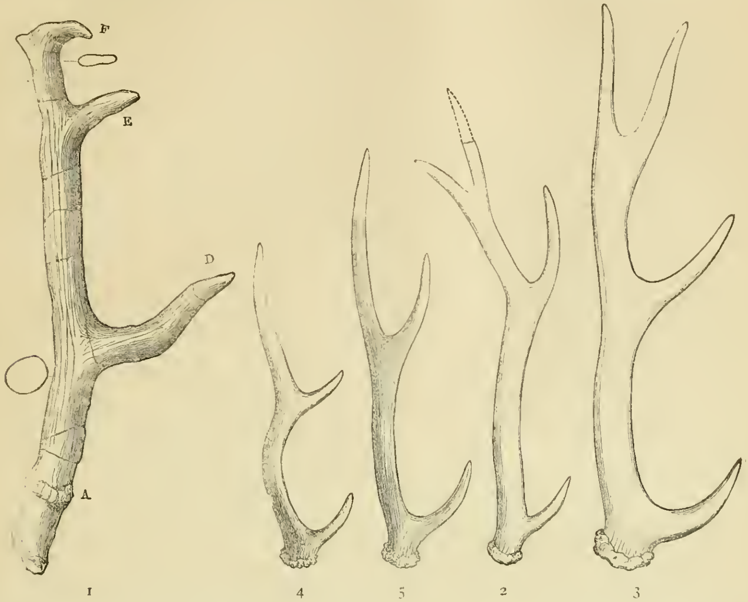


FIG. 1.—*Cervus Matheroni*, Gerv., Upper Meiocene, Mont Léberon ($\frac{1}{3}$) FIG. 2.—*C. perrieri*, Cr. and Job., Upper Pleiocene, Mont Perrier ($\frac{1}{5}$). FIG. 3.—*C. issiodorensis*, Cr. and Job., Upper Pleiocene, Mont Perrier ($\frac{1}{5}$). FIG. 4.—*C. etueriarum*, Cr. and Job., Upper Pleiocene, Mont Perrier ($\frac{1}{5}$). FIG. 5.—*C. pardinensis*, Cr. and Job., Upper Pleiocene, Mont Perrier ($\frac{1}{5}$).

in the death of the bony tissue above it. We may therefore conclude that this singular *Procervulus* type was the starting-point of the antlered Ruminants both in the Old and the New Worlds. In both, moreover, it is associated with the *Dicroceros* type. The two phases of antler development in the Mid-Meiocene age in Europe, and probably at the same age in North America, are represented by living deer, first by the transient condition of the

FIG. 6.—*C. dicranios*, Nesti, Val d' Arno ($\frac{1}{12}$).

young antler in the velvet, and secondly by the second antler in most species, and by the simple-forked upright antler of the adult muntjac.

The antlers also of the adult fallow deer (*C. dama*) present variations which can, in my opinion, only be accounted for by the doctrine of evolution. The ancestral form appears in the Pleistocene age in Britain, and is characterised by antlers palmated in front, instead of behind the beam, as in the normal living species, from which I defined it under the name of *C. Browni*, after its discoverer at Clacton in Essex. It occurs also in the gravels of the Thames Valley at Acton. Sir Victor Brooke has pointed out that some three or four specimens out of the vast number of antlers of the living form which he has examined possess

exactly the same character. Its appearance in the living form may be explained by the hypothesis of a reversion similar to that by which from time to time a horse is born with three toes, due to its descent from a three-toed ancestor. W. BOYD DAWKINS

THE GEOLOGICAL SURVEY OF ITALY

AMONGST the numerous signs of renewed life which characterise United Italy, the rapid spread of scientific research must take important rank. In its old homes at the world-famous universities, science, not often entirely neglected, is now once more largely cultivated. New Museums are springing up in many of the more important towns, and old ones are everywhere remodelled and enlarged.

Geology has its full share in this scientific revival, as a glance at the annual volumes of the *Geological Record* will show. The establishment of the Geological Society of Italy, to which we referred a fortnight back, will do much to encourage the study of this science.

The Geological Survey of Italy was established in the year 1868; since that date it has gradually developed, and has now accomplished some very important work. The Survey is at present a branch of the Corps of Mining Engineers, but we speak of the service in the phrase best known in England for similar organisations. Since 1870 twelve volumes of the *Bollettino del Ro. Comitato Geologico* have been published. These contain memoirs of various districts, often well illustrated, by members of the Survey or by other workers whose essays are considered to be worth publishing at the public expense. Probably many memoirs of the latter class will in future find their way into the Geological Society's volume, and the *Bollettino* be more purely official.

The organisation of the Survey is somewhat peculiar, and exhibits an amount of divided responsibility which can hardly conduce to its success. The service is partly under the control of a committee of eleven members and a secretary. Of this committee Prof. J. Meneghini of Pisa is president. Seven of the members are nominated by the King, chiefly from amongst the professors at the universities. These give their services gratuitously, only the actual travelling expenses being paid by the Government. The remainder are official members, and some of them are in other ways connected with the Survey.

Each member of the committee has a certain amount of influence in the control of the Survey within his own district; he is supposed to be consulted upon all questions relating to classification, naming of fossils, &c., but the surveyors are really responsible to the official chief of the Survey, M. G. Giordano. Three members of the Scientific Committee take the chief share in the direction. These are Prof. J Meneghini for Tuscany and Rome; Prof. G. Cemmellaro of Palermo for Sicily; and Prof. J. Capellini of Bologna, whose advice and assistance is always freely at the disposal of the Survey. This dual government might have been desirable in the early stages of the Survey; but now that Italian geology has made such progress, the staff so well trained, and the work so far advanced, it will probably be desirable to reorganise the Survey upon its own basis, giving the sole responsibility to its own official chief.

The surveying staff is part of the Corps of Inspectors of Mines (Ingegneri delle Miniere), the Chief Inspector of which is also the Chief of the Survey. Italy is divided into eight mineral districts—Turin, Milan, Vicenza, Florence, Ancona, Naples, Caltanissetta, Iglesias (Sardinia). The Inspectors of Mines have duties very similar to those of officers holding a like position in England. They visit and report upon mines in cases of accidents, and when any important changes take place in the working of the mines they may be called on for advice. The engineers are chosen from students trained in one of the seven engineering schools of Italy (Turin, Milan, Padua, Bologna, Pisa, Naples, Palermo). They then go for two years to a foreign mining school (Berlin, Freiberg, London, or Paris). Those engineers who are to serve on the Geological Survey Staff receive additional instruction for this purpose. Till now this extra training has generally been obtained from the Geological Survey of England, so that we may regard the Italian Survey as in a certain sense related to our own. Of the officers thus trained in England we may mention M. Anselmo, L. Baldacci, L. Mazzetti, R. Travaglia, De Ferrari, and E. Cortese; to the last named of these we are indebted for much information here given.

The basis of every geological survey must be a good topographical map. The Austrians published a map of a great part of Italy on the scale of 1 : 75,000; this however is not satisfactory. An entirely new topographical survey is now in progress; commenced in Sicily in 1862, it is gradually advancing to the north. The general map of Italy is on the scale of 1 : 50,000, with contour lines at every 10 metres. The more important mineral districts are published on the scale of 1 : 25,000, with contour lines at every 5 metres; a very beautiful map of Rome and the surrounding country is now published on the larger scale, as also are Sicily and parts of the N.W. Apennines. There is a smaller map, on the scale of 1 : 100,000, with contours at every 50 metres.

The small sum voted annually by the Italian Parliament has hitherto been spent in surveying only, and none of the maps have yet been published. They were however all exhibited at the Geological Congress at Bologna. It is expected that a larger grant will now be made, and the Survey be placed on a more satisfactory footing. The Central Survey office at Rome, hitherto lodged in the Piazza S. Pietro in Vincoli, will shortly be transferred to the handsome buildings lately erected for the Ministry of Agriculture, Industry, and Commerce.

The whole of the Island of Sicily has been geologically surveyed on the largest scale. This district is of commercial importance from its great yield of sulphur, amounting to 250,000 tons per year. The entire map of Sicily on the scale of 1 : 50,000 was exhibited at Bologna; this is a very beautiful work, and will be of great service to all students of that most interesting region. The Apennines north of Pisa are also surveyed on the scale of 1 : 25,000. This district is of great importance from the marble quarries of Carrara, Massa, &c., the yield of which is 150,000 tons per year. Great uncertainty has long been felt as to the geological age of the Carrara marble; it contains no fossils, and its exact relation to adjacent formations has hitherto been doubtful. It has at various times been referred to many different geological horizons; but now the geological surveyors seem definitely to have fixed its position in the Trias. The mineral districts of Sardinia and the Campagna of Rome have also been surveyed on the scale of 1 : 25,000.

The complete geological survey of a country is a work of some time, and many years must elapse before that of Italy is finished and its maps published. In the meantime the Survey has done a most useful work in preparing a general geological map of Italy on the scale of 1 : 500,000. For this purpose all previously published information has been utilised; the geological notices scattered through various scientific journals, Italian and foreign, have been collected and arranged by M. Giordano and his colleagues. The numerous blanks have been filled up by special researches; and the result is a valuable and beautiful map, which will shortly be published. It was desired to issue a reduction of this on the scale of 1 : 1,000,000, but as no topographical map on this scale exists, a French map was adopted, engraved on the scale of 1 : 1,111,111 (or 1 decim. to a degree). This map was corrected where necessary, and was published in time for the meeting of the Congress at Bologna. The map is issued in two

editions, one with hill-shading and one without. The only general map previously published was that of Collegno, in 1846, on the scale of 1 : 2,000,000. A glance at the two maps will show the immense advance which has been made in our knowledge of Italian geology since that date.

The map in question is coloured in accordance with the scheme recommended by the Italian Map Committee of the International Geological Congress. The Italian committee (like the English) prefer to retain some shades of red for the Trias. The Congress however, chiefly influenced by the wishes of Germany, proposes to colour this violet, as the natural base of the Secondary series; the Jurassic beds being coloured blue. The Italian Survey is desirous of adopting for its future maps the scheme of colouring upon which the Congress may decide. The Indian Survey also, being now about to publish a connected series of maps, wishes, if possible, to do the same.

We have little doubt that the geological map of Europe, now being prepared by the Map Committee of the Congress, will be so drawn up and coloured as to form a scheme of colours which can, with only small modifications, be adopted by all. W. TOPLEY

NOTES

A COMMITTEE has been formed at Reggio (Emilia) to collect funds for establishing a fitting monument to the memory of the Padre Secchi, in the form of a fine refractor, of which the objective is to have 70 centimetres diameter. Reggio thus follows the example of Arcetri, where a fitting scientific monument has been erected to the memory of Galileo.

THE Honorary Degree of LL.D. has been conferred by the University of Cambridge on Thomas Sterry Hunt, F.R.S.

M. COCHÉRY intends to spend the surplus of the Electrical Exhibition, which is said to exceed 16,000*l.*, in establishing a research laboratory for electricity.

M. PAUL BERT, the new French Minister for Public Instruction, is said to be a candidate, in the section of Medicine, to fill the place vacated in the Academy of Sciences by the recent death of Dr. Bouillaud.

IT is painful to have so often to animadvert on what must look like parsimonious treatment of science on the part of our Government. Its almost contemptuous treatment of the Electrical Exhibition and of the British Commissioners has called forth the strongest criticism; and under our Geographical Notes to-day will be found another instance of a similar kind. Lord Aberdare, who, as president of the Geographical Society, went to the recent Venice Congress as commissioner of that body, referred "to the miserable show made by this country at the Exhibition, which was solely due to the parsimony of the Treasury, who did not even pay the travelling expenses of the British Commissioners, and merely sent 100*l.* to the Vice-Consul at Venice for petty disbursement." Of course our Government had no intention of insulting the Congress and the Geographical Society; but such treatment of an International Congress on the subject in which this country is so practically interested, must seem strange to good-mannered foreigners. Our Government ought really to consider earnestly their position to such enterprises as those referred to; it is too late in the day for even England to despise anything that tends to the promotion of science.

A BRILLIANT *fête* was given at Berlin on the evening of November 19 in honour of Prof. Virchow, in the Hall of the Rathhaus, which was handsomely decorated for the occasion. About 1000 persons were present, chiefly belonging to the scientific and medical world. Prof. Bastian presided, and after calling for cheers for the Emperor, he presented the title deeds of the Virchow Institute for promoting anthropological studies, according to Prof. Virchow's own directions, and for which a sum of 70,000 marks has been collected from the various countries of Europe. Speeches were then made by the leaders of the thirty deputations present, which included representatives of the medical faculties of Aberdeen, Basle, and Charkoff, and the medical societies of St. Petersburg, Vilna, &c. Finally, a deputation from Schivelbein, in Pomerania, Prof. Virchow's native town, presented congratulations to the Professor, who returned thanks with great emotion. A supper followed, and the guests did not separate till a late hour.

THE death is announced, at the age of eighty-three years, of M. Camille Sébastien Nachet, the founder of the well-known firm of Nachet et Fils, opticians, Paris. M. Nachet, during his long career, did much for the improvement of the manufacture of lenses, and especially of microscopes.

WE regret to announce the death of Dr. Karl Peters, Professor of Mineralogy and Geology at Graz University, and author of numerous scientific papers, who died at Graz on the 7th inst., aged fifty-seven years. The death is also announced of Dr. Karl Fortlage, Professor of Philosophy at Jena University, at Jena on November 8, aged seventy-five.

THE Paris Municipal Commission has resolved to illuminate successively the Council Hall with five different electric lights, to determine the price of each, and make a choice amongst them. These five have been selected out of all the systems exhibited. The Swan and Brush systems are two of those selected for the competition. Electricity will be also used for moving an elevator of the kind exhibited by Mr. Muirhead, and a press for printing the papers used by the Council.

EARTHQUAKES have been rather prevalent on the Continent during the past week. Between five and six o'clock on the morning of the 16th three shocks were felt in Switzerland. Two were of some violence at Mendrisio, in the canton of Tessin, and one less severe in Berne and the Bernese Oberland. On the same morning, at seventeen minutes past five, a slight earthquake shock was felt at Naples, lasting three seconds. Its direction was south-east. At dawn a shock was felt at Cosenza. Two shocks were also felt throughout the province of Catanzaro at six o'clock in the morning. On the 18th at five a.m. several smart shocks were felt over the greater part of Eastern Switzerland. The centre of the disturbance seems to have been in the canton of Zürich and the Oberland of St. Gall, where the oscillations were very marked and frequently repeated. Shocks were also felt on the Friday night along the Valley of the Lower Rhine, at Coblentz, Bonn, Cologne, Aachen, Elberfeld, Barmen, Crefeld, Essen, Düsseldorf, and Duisburg, a distance of over 100 miles. There were two violent vertical shocks lasting five seconds, then wave-like tremors in the direction of north-west to south-east.

OUR Vienna Correspondent writes that shocks of earthquake occurred at Izentes and at Izarvas (Hungary) on October 28, at 4 a.m. On November 5 shocks were experienced at different places in Carinthia, viz. at Klagenfurth a perpendicular shock was felt at 9.37½ a.m.; it was followed by slight undulatory movements in the direction west-east, lasting four seconds. At Moosberg and Patermon several shocks were felt at 9.45 a.m.; direction, south-west to north-east. The shock was also felt at Villach at 9.40 a.m.; direction, south-north; at Ober-Vellach at 9.40 a.m., south-north. At Emünd four shocks occurred; the first, at 10.5 a.m., being so severe as to cause people to rush out of their houses in fright, chimneys were thrown down and the walls of some houses damaged; duration, four seconds; direction, north-south. At Spital (on the Drou) also four shocks were felt; duration, nine seconds; direction, from east-west. From Sachsenburg and Reichenan also the occurrence of shocks is reported at 9.30 a.m. at the former, and 9.45 a.m. at the latter place: the movements lasted

from four to five seconds; direction, north-east to south-west. The centre of the earthquake mentioned above seems to have been in the neighbourhood of the Millstädt Alp. At the same time earthquake-shocks were felt at Stuben, Langen, Pöhtnen, Flirsch in Vorarlberg, and at Murau and Obdach in Styria. In Switzerland shocks of earthquake occurred on November 14, at 3.35 a.m., at Villeneuve, Rivaz, Bouveret, and between five and six o'clock in the morning at Seewen, Berne and its environs.

A CORRESPONDENT of the Swiss *Bund*, writing from Vevey, says that on the morning of the 14th a large meteoric stone, which seemed to come from a point in the Hautler directly over the mountains on the Savoyard side of the Laste, fell with a tremendous report in the market-place of Vevey. It was sufficiently large to have crushed any house upon which it might have chanced to alight.

DR. T. S. COBBOLD exhibited (at the Linnean Society's meeting, November 5) under the microscope about a hundred eggs of *Bilharzia hæmatobia*. They were taken from a gentleman who had just arrived from Egypt, and who was the victim of hæmaturia, supposed to have been contracted during a shooting expedition. By adding water nearly all the eggs were hatched during the meeting of the Society, and a rare opportunity was thus afforded of witnessing the behaviour of the newly-born ciliated animalcules.

THE first step in the construction of a line of telegraph in China has been taken. On September 19 the line between Shanghai and Chinkiang on the Yang-tsze River was opened, and congratulatory telegrams exchanged between the authorities in the two places. The remainder of the line to Peking was expected to be completed within two months after that date. The cable, about two miles in length, was successfully laid across the Yang-tsze, and the line on the north of the river is now being rapidly pushed forward, following the line of the Grand Canal. Several other short cables will have to be laid across the larger creeks before the work is completed. With the exception of a line a few miles in length, between Woosung and Shanghai, which is the property of the Great Northern Telegraph Company, this is the first telegraph line laid in the Chinese Empire. When popular prejudice is once overcome, the extent to which telegraphs may be employed in China is incalculable.

IT is stated that the Chinese Government have taken measures for the immediate removal of the bar at the mouth of the Shanghai River, which has so long been a serious obstruction to navigation. At certain states of the tide ocean-going steamers are forced to remain in an exposed situation outside this bar, and all the efforts of the Foreign Ministers and mercantile communities to obtain its removal have been hitherto ineffectual. This is another example of the change which is coming over the Chinese counsels. *Apropos* of this we may mention that the ninth vessel constructed by the Chinese has just been launched at the Kiangnan Arsenal. It is a screw steamer of about four hundred tons, and is intended for the repression of smuggling and piracy. The vessels already built at the Arsenal are two frigates, four gunboats, a sailing ship, and an ironclad.

AMONG the numerous publications of the Imperial Maritime Customs of China, none are of more general interest than the half-yearly reports of the Customs medical officers. They deal, as might be expected, with various forms of disease among foreigners in China. The twenty-first number has recently been published. The writers are scattered all over the vast empire of China, from Newchwang in Manchuria to Canton, at various stations on the Yangtsze, and in Formosa. The latest issue contains papers on *Filaria sanguinis hominis* in Southern Formosa, on *Trichinia spiralis* in Chinese pork, and on skin diseases. This last is especially important, as one of the principal objections to Mongol immigration is the quantity of disease which follows. The Hawaiian Archipelago is said to suffer severely from diseases such as leprosy, small-pox, syphilis, measles, &c., which are all foreign to the islands, and have been introduced wholly by the immigrants. These papers certainly deserve more attention than they seem as yet to have received in this country.

THE disordered condition of the domestic affairs of Turkey has not prevented the Government finding leisure for the reform of its system of weights and measures. The new system which will replace the old clumsy method of computation will come into force on March 1 next, old style. It is strictly metrical, and applies to measures of length, square measure, and capacity. The measure of length will be based upon the archine, which is exactly equal to the French metre.

IN sinking for a stand-pipe for boring operations, the *Colonies and India* states, the Kilcunda (Victoria) coal prospecting party found the skeleton of a kangaroo at a depth of 28 feet. Instructions were given by the Mining Department to preserve the entire skeleton, and the jawbone was sent to Prof. M'Coy, who states that it belongs to a new species of an extinct genus of kangaroo, and indicates that the deposit which was found is of the pliocene tertiary age. The Professor says the discovery is a very interesting one, and will form a valuable addition to the public collection.

ON October 10 a fine fata morgana was observed at Rügenwalde (Pomerania). During the afternoon of that day a northern village with snow-covered roofs, from which icicles were hanging, was seen for about an hour. Human forms are also said to have been distinctly recognised. It is believed that Nexö, on the Island of Bornholm, was the village reflected.

AT the last meeting of the Linnean Society Mr. Frank Crisp was elected treasurer, and Sir John Kirk a member of the Council, to fill vacancies caused by the death of the late Mr. F. Currey.

THE great lava flow from the Mauna Loa (Hawaii), which lasted no less than nine months, has at last stopped. It began on November 5, 1880, and until August 31 last the lava had run a distance of 96 kilometres, from the summit of the volcano (which measures 14,000 feet in altitude) down the eastern slope, almost as far as the sea-coast. The town of Hilo was in the most threatening danger of being destroyed. Fortunately the force of the eruption was exhausted and the flow of lava stopped within a few thousand yards from the town. This eruption was the most colossal one ever recorded in Hawaii.

THE report of the Indian Commissioners shows the present number of Indians in the whole country, exclusive of Alaska, to be 261,912, all of whom, except 15,416, are more or less in charge of agents of the Government.

THE Conservatoire des Arts et Métiers of Paris has been removed from the Department of Trade and the Colonies and transferred to the Ministry of Fine Arts. The reason of this change is obviously the intention of developing technical education among French working men.

THE flashing system of telegraphy has been so successful in Tunis that the insurgent Arabs are powerless to stop regular correspondence between the several corps of the French army. The same system is used in Oran, province Algeria, in the pursuit of Bou Amena.

THE *Journal* of the North China branch of the Royal Asiatic Society for 1880 contains a long paper by Dr. Bretschneider, o the Russian Legation at Peking, on Early European Researches into the Flora and Fauna of China, and one by Dr. Bushell, of the British Legation, on the Coins of the Present Chinese Dynasty.

AN interesting cave has recently been discovered in the Bela Lime Alps, which form the north-eastern part of the Tatra Mountains. From the Kotlin valley the cave can be reached in about an hour. During August and September last the inhabitants of Bela thoroughly investigated the cave. The entrance is formed by a shaft about fifteen metres long and only one metre wide. After having passed this torches must be lighted. The cave contains fine white stalactites and stalagmites, large subterranean lakes and ponds, which obtained for it the name of "Seehöhle" (lake cave). A number of bones of prehistoric animals were found. It appears however that the cave was known to the neighbouring inhabitants about the years 1713 and 1731, and was then forgotten. German names with these figures underneath were in one part found scratched upon the rock.

ON September 1 an Aëronautical Society was founded at Berlin under the presidency of Dr. Wilhelm Angerstein. The new Society grows rapidly, and it is the intention of the Committee to hold an aëronautical exhibition next year.

THE additions to the Zoological Society's Gardens during the past week include a Moustache Monkey (*Cercopithecus cephus* ♂) from West Africa, presented by Mr. Frank G. S. Laye; a Bonnet Monkey (*Macacus radiatus* ♀) from India, presented by the Rev. R. H. Manley; two Herring Gulls (*Larus argentatus*), European, presented by Mrs. Greaves; two Chilian Sea Eagles (*Geranoœtus melanoleucus*) from South America, a Red-breasted Merganser (*Mergus serrator*), a Guillemot (*Uria troile*), a Bar-tailed Godwit (*Limosa lapponica*), British, purchased.

GEOGRAPHICAL NOTES

ON Monday week Lord Aberdare opened the fifty-second session of the Geographical Society with a brief address, in which he dealt first with the expedition of Dr. Matteucci and Lieut. Massari across Africa. He next referred to the geographical papers read at the York meeting of the British Association, and afterwards dwelt at some length on the International Geographical Congress at Venice. According to Lord Aberdare's view it is a great mistake to mix up exhibitions with these congresses, as, owing to international jealousies, it becomes necessary to withdraw the best men from the sections of the congress to serve on the juries of the exhibition. Lord Aberdare referred particularly to the miserable show made by this country in the Exhibition, which was solely due to the parsimony of the Treasury, who did not even pay the travelling expenses of the British Commissioners, and merely sent 100*l*. to the Vice-Consul at Venice for petty disbursements! The latter part of the address was chiefly devoted to the Arctic expeditions of the *Jeannette* and the *Eira*, and we are glad to notice that so much confidence is felt regarding the safety of Mr. Leigh Smith's party. Mr. F. A. A. Simons afterwards read a paper of considerable geographical interest on the Sierra Nevada de Santa Marta and its watershed, and he certainly has thrown much light on this almost unknown region, *i.e.* in the north-west corner of South America. The water-system, which Mr. Simons was at much pains to explain clearly, consists of the Rio Cesar, with its affluents, the Rio Rancheria and others falling into the Caribbean Sea, and the two large rivers which form the Grand Cierraga. Mr. Simons, who has spent some three and a half years in the country in natural history researches, has already contributed to the Geographical Society's *Proceedings* a paper on the topography of the Sierra Nevada, so that its geography can now be well understood through his labours.

SOME further details of the interesting discoveries made by the search ship *Rodgers* in and about Wrangel Land are given in the *Times*. It appears that the *Rodgers*, after leaving St. Lawrence Bay, passed through Behring Straits, and effected a landing on Herald Island on August 24. Having left records of her visit there, she steamed for Wrangel Land, which she reached on the evening of August 26. Finding a safe harbour, she despatched parties to the eastern and western coasts in search of cairns or traces of the *Jeannette*. Capt. Berry, who commanded the land party, reached a mountain 2500 feet high, from which he saw open water around the island everywhere, except between the west and south-south-west, where a high mountain seemed to terminate the land. Master H. S. Waring went round the eastern coast and northern side, and being blocked by ice had to return by land to the ship. Ensign Hunt went by the western coast and reached the ice which had blocked Waring, and found it impenetrable. He had passed to the northern side, and could see Waring's position, so that the entire island had thus been skirted. No traces of the *Jeannette* were found. The *New York Herald* correspondent says that he was "surprised to see the ice moving constantly to the westward along the shore, where, according to a natural supposition, the wind would blow it off. Sometimes when he went to bed he would see the pack ice filling the sea as far as the eye could reach, and the next morning when he went on deck he would behold a vast expanse of open water." Wrangel Land is now said to be about sixty miles long, and there is a current at the northern end of it running to the north-west, at the rate of about six knots an hour. At the south-east of the island the ice was observed to be drifting in a northerly direction, at the rate of about two miles a day. From all this it is inferred that the *Jeannette*, which was last seen in September, 1879, steaming towards Wrangel Land, did not reach that island, and that either she was caught in the pack, and is being carried by the current in a northerly direction, at about the 172nd meridian, or that, finding the sea open, as the *Rodgers* did, she has been induced to leave the land, and has taken advantage of open leads through the ice, and has sailed northwards into unknown space. Efforts are still being made to search for her or her crew if they have abandoned their ship. The *Rodgers* will winter at St. Lawrence Bay off Kotzebue Sound, on the Alaska coast, and will in the spring make further search. The American observation party have reached Point Barrow, where they will winter, and where they will have opportunity of searching among the wreckage, which is so often washed on that shore, for any records of the missing ship.

LIEUT. A. HOVGAARD, who was on Prof. Nordenskjöld's staff in the memorable *Vega* expedition, is trying to start an expedition in search of the *Jeannette*. Hovgaard thinks of sailing in the same track which was pursued by the *Vega*, in order to prove that the Kara Sea is perfectly navigable, if the necessary precautions are taken. He intends to winter at Cape Chelyuskin, in order to make scientific and principally meteorological observations. He has already received numerous contributions for this purpose from his Danish compatriots.

COUNT WALDBURG-ZEIL has safely returned from his Arctic expedition, which had for its object the establishment of a regular steamship service between Bremen and Siberia. His ship *Luise* encountered considerable difficulties; nevertheless the Count is of opinion that a regular service will be possible and remunerative. The *Dallmann*, the second ship of the Count's expedition, was left behind at the Yenisei estuary, where it will remain during the winter.

THE German paper *Ausland* publishes a letter from the German traveller Dr. B. Hagen, dated from Tandjong Morawa, to which he had returned from his excursion into the interior of Sumatra. He travelled through the Northern Batta districts, hitherto almost entirely unknown, and then across the plateau of Northern Tobah as far as the great Tobah Lake. The traveller was well received everywhere, and only the eternal wars between the several villages impeded and delayed his progress. His collections of anthropological, ethnographical, zoological, and particularly of botanical specimens are very large. The fauna and flora on the Tobah Plateau, as on all tropical high plateaux (such as Java, and even in Japan), resemble those of Europe.

NEWS from Zanzibar state that the Belgian expedition under Mr. Rogers left for the Congo on October 20 last, 135 natives accompanying it.

UNDER the Chefoo Convention, negotiated by Sir Thomas Wade with the Chinese authorities in 1876, it was agreed that a British officer could reside at Chung-king, in Sze-chuan, on the upper waters of the Yangtsze. The gentleman at present stationed there, Mr. E. H. Parker, of H. M.'s Consular Service in China, seems to have made good use of the opportunities thus afforded him of investigating this comparatively little-known district. Under the title of "Short Journeys in Sze-chuan," he has contributed to recent numbers of the *China Review* an account of his travels in the province, together with observations on its trade, customs, geography, &c.

THE PRESSURE ERRORS OF THE "CHALLENGER" THERMOMETERS[1]

I.

I. *The Pressure-Corrections supplied to the "Challenger" along with the Thermometers*

WHEN I was first asked to examine the thermometers I judged, from the appearance and nature of the protection over the bulbs, that very slight corrections only would be required, even for the greatest pressures to which they had been exposed. But Sir Wyville Thomson told me that a correction of at least half a degree Fahr. had been assigned for them for every mile under the sea. This correction had been given him by Capt. Davis of the Admiralty, who had in his experiments[2] the assistance and advice of such exceedingly able experimenters as the late Prof. W. Allen Miller and others.

Hence, although it appeared to me at first sight incredible that any such correction should be required for thermometers with protected bulbs, I considered it absolutely necessary to try Capt. Davis' experiments over again, under the same conditions as those which he had adopted in conjunction with Prof. Miller. My object was, of course, to find out whether I could again obtain these results, and, if I could obtain them, to discover what were the causes which led to their being so exceedingly different from what I should have expected. I felt assured that the results were much too large;—and I had therefore, if I could reproduce them, to trace the various possible causes of divergence between the results of experiments conducted in a hydrostatic press and of other similar experiments made at the same pressures in the deep sea.

Half-a-degree Fahrenheit per mile of depth may seem to be a matter of very little consequence; but when we recollect that some of the *Challenger* soundings were made at depths nearly approaching six miles, we find that we have sometimes to deal with a correction of 3° F., enough to modify seriously our theories of ocean circulation. For it can never be too strongly impressed on the student of science that there is no such thing as greatness or smallness in itself; what is very small relatively to one class of quantities may be very great relatively to another and different one. All the temperature differences, except near the surface of the sea, though important in their consequences, are very small relatively to differences of temperature in the atmosphere; but, just because they are so small, small errors in the determination of their values are important:—thus it was imperative to decide whether the corrections assigned by Capt. Davis are necessary.

At first sight one might think that by far the best way of conducting an inquiry of the kind would be to carry it out under circumstances nearly the same as those of the *Challenger* observations. No doubt, if we had at hand a coal-pit or mine-shaft full of water, and of six miles or so in depth, we might make the experiments without the aid of presses, and under circumstances far more favourable than those in which I was obliged to operate. The reasons for this statement will appear presently. There are great objections to making test-observations at sea. The *Challenger* observations themselves had, of course, to be made at sea, but to make under similar circumstances experiments for the purpose of determining corrections would be a perfectly hopeless attempt. The circumstances under which thermometers are let down and drawn up again at sea are extremely unfavourable to accuracy of observation. I had, therefore, to content myself with such conditions as could be procured by means of hydrostatic presses.

II. *Construction of the Thermometers.*—I will now say a word or two about the construction of the thermometers themselves; and I shall thus have an opportunity of pointing out some of the peculiarities of construction to which I have traced the greater part of the very large effects obtained by Capt. Davis, and given by him as corrections which required to be made.

The *Challenger* thermometers are all of the Six pattern: there is a highly expansible liquid in the large bulb, which projects to a certain extent into the narrow U-tube. Then there is a column of mercury occupying the bend of the U and part of each stem. Above that, on the maximum side, there is some more of the sensitive liquid; and at the ends of the mercury column are the maximum and minimum indices, each containing a piece of steel, so that they can be set by means of an external magnet. The large bulb on which the temperature effects are mainly produced is protected by an exterior shell of glass strong enough to resist a pressure of at least 5000 fathoms of sea-water; that is to say, approximately, somewhere about six tons weight per square inch. This external shell is nearly filled with alcohol. The main difference between this and the first invented form of protected thermometer, which (so far as I know) was introduced by Sir William Thomson,[1] is simply that the bulb only is protected, the stem being exposed, and therefore the effects produced directly by compression are due solely to the stem of the instrument; unless, indeed, there be a strain produced on the protected bulb (altering its volume) by the wry-neckedness of the protecting shell.

Now, as a rule, till quite recently, practical workers in glass supposed that no effect at all would be produced by pressure upon an ordinary thermometer stem, simply because the external diameter is so much greater than the internal; and, in fact, so little was the nature of the effects of hydrostatic pressure known to practical glass-blowers that one of Mr. Casella's workmen undertook in 1869 to furnish Capt. Davis with thermometers whose bulbs should be so thick as to "*defy compression*"! It will be seen presently that such an idea is entirely absurd:—that, however thick is an unprotected thermometer, it will still have its indications altered by compression, and very nearly as much as a thinner one, unless that be extremely thin. So far as the *Challenger* instruments are concerned, the only effect that can be expected to be produced directly by pressure is the diminution of the bore and length of the narrow tube, and the consequent forcing of the liquid which occupies it to fill a greater length in it. I made at starting a rough calculation of the amount of effect of this kind which was to be expected; taking average data as to the compressibility and rigidity of glass. I found it to be a small fraction only of a degree for each ton-weight of pressure, except on those thermometers which had very short degrees. It was clear to me, therefore, that (unless the wry-neckedness already mentioned was the cause) the larger part of Capt. Davis' result was not due to pressure directly.

III. *Wholly Protected Instruments. Their Defect.*—For the purpose of comparison with the *Challenger* instruments, so far as regards the effect on the unprotected stem, Sir Wyville Thomson sent me two mercury thermometers constructed after Sir William Thomson's device. In these instruments the whole, bulb and stem alike, is inclosed in a strong glass tube, nearly filled with alcohol. The effects of pressure on these instruments were very much smaller than on the thermometers of the *Challenger*. This result was so unexpected that I at first thought it due to defects in the new instruments. But, as will be seen later, it is quite consistent with the final result of my investigations. It is, however, very difficult to obtain good results from these instruments under the circumstances in which I was working. Their recording adjustment is constructed on a new plan, in which a little portion of mercury is detached from the rest; and separated from it by a small quantity of air, which does not move it until compressed to a definite amount. To set the index before an observation, the instrument has to be swung round somewhat sharply at arm's length. It was scarcely ever possible under these circumstances to adjust it to the temperature of the water in the press. The indices in the *Challenger* thermometers, on the other hand, consist each of a piece of enamel with a couple of hairs attached to it so as to fix itself in the tube and retain a record of the observation. They have also a little piece of needle inside, and can thus be moved from the exterior by means of a horse-shoe magnet, so that the adjustment can be made at pleasure, and without any alteration of the temperature. The thermometers are plunged for some hours in the water in the press, and the indices are set in an instant while the instrument is partially lifted out for the purpose. With the other instruments one might spend days before he could get them

[2] "On Deep-Sea Thermometers," by Capt. J. E. Davis, R.N. (*Proceedings* of the Meteorological Society, April 1871).

[1] "The Effect of Pressure in Lowering the Freezing-point of Water experimentally demonstrated," by Prof. W. Thomson (*Proc. R.S.E.*, February 1850). See also the paper by Parrot (1833) quoted below. In this a protected thermometer was undoubtedly employed; but the protecting sheath was part of the wall of the compression apparatus and was not attached to the thermometer itself. From a reference in this paper I was led to consult Lenz' observations on deep-sea temperatures. He appears to have measured these temperatures by bringing to the surface, with great care, a considerable quantity of water from each depth. There was a thermometer in the collecting apparatus, with a bulb of extra thickness; but no recording index was employed, so as to show what was its indication under pressure.

introduced, except after special cooling, into the press with the index suitably adjusted to the temperature of the water. The whole difficulty might have been avoided by putting an exceedingly small piece of iron or steel wire above the index, to be acted on by a sufficiently powerful magnet.

Thus, although these instruments are absolutely perfect so far as regards immunity from pressure (and in other essential respects which will be mentioned later), it is not easy to work with them under the circumstances of this investigation.

IV. *Individual Peculiarities of some of the "Challenger" Thermometers.*—The *Challenger* thermometers are not all exactly similar to one another. Some of them have their degrees very much longer than others; others have the extraordinary peculiarity that the degrees upon the maximum side are nearly half as long again as those on the minimum side, and sometimes it is the reverse. In one of the instruments which was occasionally used in the deep sea, the length of a single degree on the maximum side is only about three-fourths of a millimetre, and thus a reading to a tenth of a degree is not to be looked for. But on account of this unexpected peculiarity this particular instrument was of use, as will be seen later, in demonstrating that the effects produced in the press were due partly to heating, partly to compression. Several instances of useful peculiarities of a similar character were detected, and utilised.

In fact, the instruments cannot be said to do more than furnish rough and ready means of approximating to temperatures within about a quarter of a degree, or in the most favourable circumstances a tenth of a degree Fahrenheit. Had they been more nearly what would be called "scientific" instruments, they might have altogether failed on account of the rough treatment to which they were necessarily subjected during use. Letting them down into the sea presents in general no great difficulties, but when they have to be hauled on board again they are subject to jerks and shocks, and sometimes swing through large arcs at the end of the lead line. Such misadventures are unavoidable at sea, and are excessively unfavourable to accurate results, because the index is necessarily not fitted so tightly in the stem that it may not in a few oscillations be sensibly displaced. And there is a defect inseparable from the use of movable indices:—viz. that the reading of the mercury column is sensibly different according as the index is, and is not, in contact with it. The capillary convexity affects the maximum and minimum indices in *opposite* ways.

Further, I may observe (though it does not affect my work) that in these thermometers the scale is at some distance from the mercury in the stem, and no provision is made for avoiding parallax or personal equation. By merely altering the position in which one holds the thermometer, it is possible to read the temperature whether by the mercury column or the end of the index next it, to an amount different in some of the thermometers by as much as a quarter of a degree, and in the great majority of them by as much as a tenth. Thus if we get readings consistent within a tenth of a degree we get all that the instruments are capable of furnishing. I have therefore always read the thermometers in exactly the same position and (when so much accuracy was attainable) only to the nearest tenth of a degree. And I have always made my comparisons between successive positions of the index; the only readings of the mercury directly being taken roughly to find whether any permanent temperature-change had been produced in the water of the press by pressure or otherwise, during the course of an experiment.

A great many different materials were tried for the framing of the thermometers: and vulcanite was finally chosen, having been found to answer the purpose exceedingly well. Wood warped, and metal was unsuitable for various reasons. It is rather curious to find, as will be seen below, that this substance was one of the main causes of the very large amount assigned to the pressure-correction.

V. *Capt. Davis' Mode of Testing; and his Correction for the Maximum Side.*—It is necessary to look somewhat closely into the mode in which Capt. Davis conducted his experiments, in so far at least as it differs from the one I afterwards employed; in order that we may be able to form an idea how, with nearly all the facts before him, he yet failed to get their proper interpretation. Take, for instance, the way in which he attempted to determine the correction which is due to the heating of water by compression. This, of course, affects the thermometers while in the hydrostatic press, but *not* when they are let down into the sea. When the water in the press is compressed with the thermometers in it, it becomes hotter as the pressure increases (so long at least as its temperature is above 4° C. or 39°·2 Fahr. that of its maximum density). This is quite analogous to the heating of air in a cylinder when a piston is suddenly forced down; when, as every one knows, tinder can be kindled by the heat developed. So water is heated by compression, but not to anything like the same extent. But it is necessary to remark that the amount of heating of water by a given compression depends in a very curious manner upon the original temperature of the water. For water taken at its maximum density is neither heated nor cooled by compression, but it is heated by compression if it is at a temperature higher, and cooled if it is at a temperature lower, than that of the maximum density. One set of Capt. Davis' observations were made in water at temperatures near, but under, the maximum density point: in which, therefore, very little effect can be produced, even by very great pressure (and that little should be cooling, not heating), and he combined these with a number of other observations made at temperatures approaching 55° F., in which a comparatively large amount of heating is produced even by moderate pressures. The average of the results of these determinations was taken, but, unfortunately, Capt. Davis struck out before taking the average all those observations which appeared to give much larger effects than the others, taking them as being obviously erroneous.

When we sift out from the observations all those made nearly at any one temperature we find they agree fairly enough with the theoretical result of the compression. But observations made at different temperatures were included in the group from which the average effect was deduced. Such an average has no physical meaning.

Capt. Davis concluded from two sets of observations, one at 55° F. and the other about 39° F., that little attention need be paid to the heating of water by compression, and thus that the effect observed in the hydraulic press was due mainly to direct pressure, and would, of course, be experienced by the thermometers when they were let down into the sea.

The officers who managed the thermometers of the expedition, were, in consequence, furnished with corrections for each thermometer, all of the order already indicated, *i.e.* about half a degree for each mile under the surface of the sea. These corrections were, of course, for the *maximum* side of each instrument.

VI. *Consequent Correction for the Minimum Side.*—Looking at the thermometers, it seemed to me perfectly evident that this correction, if it was to be applied at all, must be applied in very nearly the same amount both to the maximum index, for which it was determined, and also to the minimum. Any difference between these two must be due solely to the effects of temperature upon the column of mercury which lies between the two indices, and of pressure on the tube containing that mercury. Unless the heating effect were *confined* to the space between the indices, the former is provided for by the graduation of the instrument itself; and it was quite certain that the two together could not produce an effect amounting to more than a small fraction of the degree and a half for three tons pressure.

Therefore, as all the readings of the *Challenger* thermometers were taken from the minimum index, they were subject, according to my interpretation of Capt. Davis' results, to a correction of very nearly half a degree Fahr. for every mile of depth.

Now, even if the heating effect on the water in the press had been correctly determined, the result would have led to a deduction of at the utmost only about one-fourth of the whole correction, thus still leaving a very formidable correction indeed.

VII. *Theoretical Determination of the Direct Effect of Pressure. Experimental Verification.*—I therefore calculated the effect of pressure on a thermometer tube, assuming the best data for the compressibility and the rigidity of glass. The result, so far as is required for the present argument, is that the internal capacity of a glass tube (whose walls are thick in comparison with the diameter of the bore) is reduced by about 1-1000th part for each ton weight (per square inch) of pressure applied from without; the ends being closed. Hence, if such a tube be partly filled with mercury, with an index above it; the index should be displaced by 1-1000th of the length of the column of mercury for each ton weight of pressure applied to the outside of the tube.

I tried the experiment with a thermometer tube, the length of the mercury column being as nearly as possible a metre, and I found for every ton-weight of pressure to which the tube was exposed the index was displaced by one millimetre, the 1-1000th part of the length of the column precisely, being far more nearly than I had expected the result I had already calculated from

theory. Since, then, there is only a change of one-thousandth in the length of the column, it is quite obvious that the amount of effect produced upon the column of mercury in the *Challenger* thermometers (which is not above a sixth or a seventh of a metre in length at the utmost), that is to say, the whole correction-difference between the maximum and minimum indices is a matter of a sixth or seventh of a millimetre; or in general very nearly the same fraction of a degree of the scale. Thus it is proved that the correction supplied by the Admiralty, if it is to be applied at all, ought to be applied almost in its entirety to the minimum index.

VIII. *The Aneurisms. Their Object and Effects.*—There is another peculiarity of the *Challenger* thermometers, which leads to a slight—but only a slight—modification of this statement, viz. that at the lower end of each of the two vertical columns there is an aneurism on the tube These form a sort of secondary bulb, making the tube faulty again after the primary bulb has been protected Their effect is slightly to increase the effective length of the column of mercury.

I learned from Sir George Nares that the object of these aneurisms, and of another which is situated close to the bulb, is to prevent the indices from being jammed at the bends of the stem, or forced into the bulb, when the instrument is expoed to very high or very low temperatures. They seem to be in every respect objectionable, especially as the necessity for them would be entirely removed by adding an inch or two to the length of the instrument; or, if they must be retained, by *protecting* them and using more powerful magnets. Their presence produces an effect large compared with their apparent importance. The sketch below represents, on a large scale, one of the most highly developed of the more effective of these aneurisms, that which is situated close to the main bulb of the instrument.

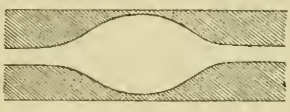

FIG. 1.—The chief Aneurism.

By reason of the convexity of the thermometer tube the diameter of the bore appears from the outside to be considerably larger than it really is. In fact a very simple geometrical construction shows that the ratio of its apparent diameter to its real diameter is that of the refractive index of glass to unity, *i.e.* it appears to be about 1·6 times its actual diameter. So that even when the aneurism, and the liquid filling it, appear to occupy the whole diameter of the tube, they only occupy $\frac{1}{1\cdot6}$ or about two-thirds, so that even in this extreme case the walls of the aneurism are not usually very thin. The percentage diminution of volume of the middle portion of the aneurism is in such a case (roughly) 50 per cent. greater than that of the unaltered tube.

The real mischief done by the aneurism is not due mainly to thinness of the walls and consequent greater liability to distortion by pressure; it is due to the fact that the aneurism, in consequence of its greater section, contains a much larger quantity of mercury than does an equal length of the tube; and therefore that a small percentage diminution of its volume will produce a marked displacement by the outflow into the narrow tube. Several of the aneurisms I have measured produce a disturbance of the index corresponding to that produced by at least five times their own length of the tube.

In some of the more exaggerated ones it actually produces an effect on the maximum and minimum index equal to that due to the extension of very nearly one-half of the mercury column in the thermometer. But this, though easily remediable, is not a defect of much consequence.

IX. *Imploding and Exploding of the Thermometer Bulbs.*—In connection with the breaking of some of the thermometers, as a result of pressure whether in the press or in the sea, it may be well to describe the curious nature of the effects produced by pressure upon the material of a tube, according as the pressure is applied from without or from within.

First, with regard to the thermometers themselves, which are exposed to external pressure, but have comparatively very slight pressure applied in the interior of their bore; and second, the corresponding effect when pressure is applied, as in the press itself, from the inside and tends to stretch the walls. [This second case has occurred with one or two of the *Challenger* thermometers also. Its source is usually defective strength of the terminal bulb of the maximum end of the tube. This bulb implodes, then the pressure is applied to the *interior* of the protected bulb, which, in its turn, explodes.]

In the diagrams below, the first three figures refer to part of the walls of the glass tube, which is exposed to pressure from the outside, but has no corresponding pressure applied within.

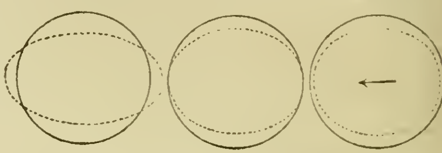

FIG. 2.—Distortion due to external pressure.

The effects of pressure indicated are those in a transverse section of the tube. The circles represent (on a large scale) transverse sections of very small spherical elements of the glass wall of the tube, the first close to the outside, the second in the middle of the wall of the tube, and the third close to the inner surface. The ellipses which are drawn along with the circles represent (of course, with much exaggeration) the corresponding transverse sections of the ellipsoids into which the spheres are distorted by the external pressure. The sphere near the outside is compressed in all directions, but much less in a radial direction than it is in a direction perpendicular to the former. The greatest amount of compression is tangential as it were, and the circular section of the sphere has been compressed into an ellipse which has a major axis in the radial direction very nearly equal to its original length, while the minor axis is very considerably reduced. The second figure refers to a small spherical portion inside the glass wall originally situated at a distance from the axis equal to 1·6 times the internal radius of the tube. (It is curious that the number 1·6, though obtained from a totally different source, should be so nearly the same as that already quoted as the refractive index of the glass.) The little spherical element at that place suffers no radial compression, but there is considerable tangential compression. Close to the interior surface of the glass tube we find large compression in a tangential direction and actual extension in the radial direction. These diagrams have been purposely exaggerated to make the effects visible. They represent what would be the effect of a pressure of 650 tons weight per square inch, provided glass could stand such a pressure and still continued to follow Hooke's law; and the outer radius of the tube has been taken as 2·2 times the inner. But they give all that is really required, viz. the *character* of the distortion at different points in the wall of the tube.

The next three figures represent the corresponding changes in

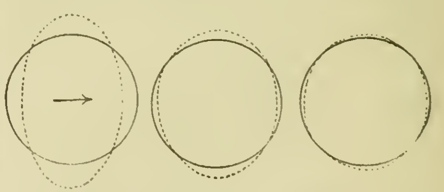

FIG. 3.—Distortion due to internal pressure.

spherical elements of the same cylindrical tube exposed to pressure from within. All portions of the tube are now extended tangentially and compressed radially, but the amount is greater on each layer as it is nearer the interior surface.

It is now easy to see how it is that a glass tube is broken by the application of pressure from without. The effect is, of course, produced first at the interior surface. For the compression is the same for every portion of the glass, but it is accompanied by shear, which increases towards the inner surface; and it is

probably the resulting extension which produces the effect. But when a tube is exposed to pressure from the interior there is dilatation of the walls, which aids the shear. Thus we see why a thin tube is so much more capable of resisting external than internal pressure. It is probable that, in the case of glass, the element which first gives way is not so much crushed as torn asunder. If so, the tube which is compressed from without is in a much more favourable condition for resisting than that in which the pressure is applied internally. For, in the first, the whole substance of the walls is compressed, and thus the linear extension produced by the shear is in part counteracted. In the second, the whole substance is expanded, and the linear extension due to the shear is aided. As will be seen in Appendix A, the case of very thick tubes is considerably different.

X. *Description of the Apparatus for applying Pressure.*—Sir Wyville Thomson handed over to me, with the thermometers, a press which was made for him before he started in the *Challenger*, and which he had carried all round the world; but when we made some preliminary experiments with it, we found it to be objectionable in many ways. It was in the first place not safe at high pressures, although an attempt had been made to strengthen it by surrounding it with massive rings of Swedish iron. As the experiments had to be conducted in college, and to a great extent by students who volunteered their services, this was a fatal defect; though I believe that the danger from the bursting of a hydrostatic press has been usually very much exaggerated. The bursting of the cylinder itself would probably be unattended with danger; but some of the nuts and connecting pieces had occasionally been projected with great violence.

A slight numerical calculation shows that a cubic foot of water at a pressure of one ton weight to the square inch is capable of doing only about 1210 foot lbs. of work in expanding, the reason being that although the pressure is intense, the amount of compression it produces is exceedingly small. But a cubic foot of air at a pressure of a ton weight to the square inch is capable of doing nearly 1300 times as much work in expanding. Hence the danger of having large quantities of air in the press before the compression is begun.

Another defect of the apparatus was the comparatively small interior bore, which did not admit of the proper carrying out of my scheme for measuring pressures—the Bourdon gauge having shown itself quite untrustworthy. Besides, two thermometers, at most, could be exposed to pressure simultaneously, even when no gauge was inserted along with them.

The apparatus which Sir Wyville Thomson finally obtained from the Woolwich gun factories, through the intervention of the Admiralty, was in fact a Fraser gun with a few adaptations made to suit it to the purposes of the investigation. The gun was made of a cylinder of mild steel, round which were shrunk two successive wrought-iron coils. The effective interior is 4½ inches in bore, and nearly 4 feet long.

This cylinder was guaranteed to be safe under pressures up to 18 or 20 tons weight per square inch, and we have for various purposes already worked up to pressures of 11 and 12 tons.

The rest of the apparatus, to fit it for our immediate purpose, consisted of a tightly-fitting steel plug which was forced into the upper end of the cylinder after the thermometers and other apparatus had been inserted, and the whole had been filled with water. The plug was forced down by the weight of an assistant standing on it, while a stop-cock at the bottom of the cylinder was kept open for the escape of water, until a massive steel key could be put in through a slot in the side of the cylinder to lock the plug in its definite position.

To the lower end of the steel cylinder were adapted a series of fittings by means of which it could be connected with a powerful force-pump, and simultaneously with a gauge whose construction will be afterwards described. The gauge enabled the experimenters to know at every stage of the operation what amount of pressure had been reached in the interior of the cylinder. The pump was worked at first by hand. Of late a more powerful pump has been procured, and it can be fitted when necessary to the gas-engine of my laboratory.

Only one real difficulty was met with in working this apparatus; viz. the difficulty of making the plug fit perfectly tight. At first, when it came from Woolwich, the plug was finished by a piece of leather in the form of a cup; but this was found to leak seriously even at very moderate pressures, so that even the comparatively small pressure of a ton weight per square inch was unattainable.

But by taking off the leather from the plug and furnishing it with a ring of steel turned into cup form with an exceedingly thin and sharp edge, on the same principle as that on which the piston of the pump was constructed, this difficulty was completely got over. The flexible steel edge was pressed against the interior of the tube more forcibly the greater the applied pressure, and it was found that the apparatus was then, except under the most unfavourable circumstances, perfectly tight, at least so far as the plug was concerned. Very great care was, however, requisite in cleaning the plug and the upper part of the bore of the cylinder before each experiment. The smallest fragment of cotton-waste, getting behind the edge of the cup, almost invariably produced serious leakage when high pressure was applied. The cup form was objectionable for one reason, that it always took down a considerable quantity of air, of which it was impossible to get rid. This difficulty was overcome by putting into the cup a quantity of tallow which completely filled it up and projected considerably below it, so that the apparatus, when pressure commenced, contained at the most a few small air bubbles only.

Later, when I found it was impossible to obtain certain necessary data, on account of the slowness with which pressure was got up in so large an apparatus, I procured a very much smaller apparatus of similar character, in which the cylinder was only an inch in bore, and rather less than a foot in effective interior length. With this apparatus two or three strokes, only, of the pump were required to get up the desired pressure, and there was the great additional advantage that temperatures could be independently measured by means of thermo-electric junctions. [This could not be done in the large cylinder without seriously affecting its strength, and rendering it at the same time almost unmanageable.]

(*To be continued.*)

TRANSFORMATION OF OLD COINS IN A LAKE

M. DAUBRÉE read an interesting paper on this subject at the Paris Academy of Sciences on October 17.

In the commune of Flines-les-Roches, canton of Douai, there is a small lake of very limpid water, known as the Mer-de-Flines. It is of circular shape, and about 300 m. in diameter; its surface remains stationary in position, and neither springs supplying it, nor any outlet, are apparent. The depth at the centre has not been determined. There are fishes in the lake, and the water attracts numerous bathers. Among other shells on the banks, one observes many specimens of *Unio*. The water rests on Tertiary strata of the Landenian formation, consisting of sand and gravel, with dark ashes and pyrites.

According to the researches of MM. Termink and Loustan, this lake appears to have been, in ancient times, a place of sacred resort, and various precious objects were thrown into it, as an offering doubtless to some divinity. Numerous coins, more especially, have been recovered, along with statuettes of bronze and much pottery *débris*. Of the coins, some are Gaulish, but the majority are Roman, of the time of the early Empire. They are mostly bronze, but some are of gold.

Some remarkable changes have occurred in many of these coins, and have been brought to the notice of the French Academy by M. Daubrée. The coins have been attacked and are completely enveloped with a crystalline substance formed at their expense. Their general aspect recalls that of the coins incrusted with metallic minerals, found in various thermal springs, notably at Bagnères-de-Bigorre, at Bourbonne-les-Bains, and at Baracci in Corsica.

An extremely fine external pellicle, of the brass-yellow colour which characterises chalcopyrite, first attracts notice. But the incrustation is mostly formed, to a depth of 2 mm., of a dark crystalline substance, with metallic lustre, consisting of sulphide of copper, and it is to it that the crystalline forms belong, which one might be apt, at first sight, to attribute to yellow sulphur.

The central part consists of a laminated substance. Here and there may be observed small dark hexagonal metallic crystals, in which one can see the characteristic striæ of chalcocite. The same substance forms small brilliant leaves, alternating with the dark leaves, on which appear some deposits of bright green. Heated in a tube, the crystalline substance gives a very slight sublimate of sulphur, which apparently results from the mixture of a little pyrites. The sulphide contains neither tin nor zinc.

The form of the exterior substance is that of hexagonal plates bearing truncated pyramidal faces inclined about 127° to the base. The cleavage is basic. This latter character and the

absence of macles appear to indicate the variety of chalcocite called *cuprein* by Breithaupt.

All these coins were buried in a dark brown mud, containing numerous shells, many of which have been involved in the sulphurated deposits. From analysis of a sample of the water obtained at 6·70 m. depth, it appears that, as in the thermal springs above referred to, there are no sulphides, but merely sulphates, which organic matters reduce to the state of sulphides.

The novelty in production of the chalcocite in question arises from its occurrence apart, seemingly, from thermal springs, and at a lower temperature than in the cases hitherto known.

OUR ASTRONOMICAL COLUMN

THE GREAT COMET OF 1861.—The long series of observations of this splendid comet has been very ably discussed, with the view to the determination of the most probable orbit, by Heinrich Kreutz, a pupil of Prof. Schönfeld of Bonn, and the investigation is made the subject of an inaugural dissertation in July, 1880.

The comet was discovered on May 13 by Mr. John Tebbutt of Windsor, N.S.W., but the first accurate observations for position were made at the Observatory of Sydney on May 26. On June 10 it was observed at Santiago di Chile, and on the following day at Rio de Janeiro. European observations commenced on June 30, and were continued until May 1, 1862, the later places being obtained by M. Otto Struve with the 15-inch refractor at Pulkowa: the comet was not followed at other observatories beyond February 3, when Prof. Julius Schmidt last observed it at Athens. The number of separate observations collected for the determination of the orbit exceeds 1150, and these extend, as will be seen, over a period of 11½ months, in which the comet traversed an orbital arc of more than 155°. Seeling's ellipse (period 419⅓ years) is adopted in the calculation of an accurate ephemeris for the whole extent of visibility, and the observations, freed from the effects of parallax and aberration, are compared with this ephemeris for the formation of normal places. The best available positions of the comparison-stars were previously brought to bear upon the observations, so that they have received at the hands of M. Kreutz a general revision and rectification, proportional weights being applied after a criticism of the observations at the different observatories, forty-one in number. Thus thirty-one normal positions between 1861, May 28, and 1862, April 23, were formed. The next step was the calculation of the planetary perturbations for the whole interval, and it was found that the attraction of Venus, the Earth, Jupiter, and Saturn were alone sensible; June 12 was taken for the commencement of the perturbations. The normal places being corrected for their effect, sixty-two differential equations were formed, and their solution by the method of least squares gave the definitive corrections required by Seeling's orbit, which it may be stated proved sufficiently near the truth to render provisional correction unnecessary. The orbit which the comet was describing on June 12, or about the perihelion-passage in 1861, is thus found to be as follows:—

DEFINITIVE ELEMENTS OF THE GREAT COMET OF 1861.

Perihelion passage, 1861, June 11·543949 M.T. at Berlin.

Longitude of perihelion	249° 4′ 58″·7	M.Eq. 1862·0
,, ascending node ...	278 58 53·4	
Inclination	85 26 15·3	
Eccentricity	0·9850773	
Perihelion distance	0·8223838	
Semi-axis major	55·1096±0·0330	
Period of revolution	409·40±0·367 Julian years.	

It will be remarked that the probable error of the resulting period is strikingly small.

M. Kreutz defers for the present an examination of the possible effects of planetary perturbation during the last revolution, in view of identifying the comet amongst those observed in the fifteenth century. If, however, the perihelion passage occurred in the winter it is by no means certain that the comet would be sufficiently conspicuous and favourably placed to be remarked in Europe. The following figures will afford an idea of the difficulty that would attend observations in these latitudes during the winter season. Assuming the comet to have been in perihelion twenty days earlier we have these positions for the respective dates (Eq. of 1861):—

	R.A. °	Decl. °	Distance from Earth.	Intensity of light.
Oct. 20	239·7	−17·3	1·53	0·52
Nov. 20	257·0	−20·2	1·77	0·39
Dec. 20	274·1	−20·8	1·88	0·35
Jan. 20	291·5	−19·3	1·86	0·36
Feb. 20	308·5	−15·8	1·70	0·42

In 1861, when the comet appeared as bright as a star of 4·5 mag., the intensity of light was 1·5, and it was just perceptible to the naked eye, when the intensity had descended to 0·4, but there was still a tail of 2½ degrees to distinguish it from a star, which would hardly be the case in the winter.

THE SATELLITES OF MARS.—In No. 2934 of the *Astronomische Nachrichten*, Prof. Asaph Hall has given data for ephemerides of the satellites of Mars at the opposition of 1881. The N.W. elongations take place with the following values of *u*, corresponding to the argument of latitude:—

Nov. 22	331°·7	Dec. 4	330°·3	Dec. 16	327°·1
26	331·4	8	329·4	20	325·8
30	331·0	12	328·3	24	324·5

From Prof. Hall's values of *u* it will be found that true N.W. elongations of *Deimos* occur Nov. 26·4411, Dec. 1·4886, Dec. 6·5350, and S.E. elongations Nov. 24·5480, Nov. 28·3340, Nov. 29·5957, and Dec. 3·3793 Greenwich times. On November 26 the distance of *Deimos* from the centre of the primary at elongation is 48″·7.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The last report of the Higher Local Examinations shows that in Group E (Natural Science subjects) there was a falling off of ten candidates and of two first classes this year. The examiners in Geology and Zoology give a generally favourable report. In Chemistry the practical work done was inferior, and common simple salts were not known by sight. Physiological Botany was little known; and the same remarks applied to Histology in the paper on Animal Physiology. In Group D, Political Economy showed much success, especially among some of the better candidates.

Dr. Latham and Mr. D. McAlister have been appointed members of the State Medicine Syndicate; and Mr. McAlister has been also appointed a member of the Board of Medical Studies.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, November 17.—Sir J. Lubbock, Bart., in the chair.—Sir John Kirk, K.C.M.G., was elected a Councillor, and Mr. Frank Crisp Treasurer, in place of Mr. F. Currey, deceased.—Mr. George Murray exhibited (for Col. Turberville), a bough of *Pinus pinaster*, with suppressed internodes of the lateral branches, the result of injury to the axis from which they sprang.—De Francis Day showed examples of the stomach of the pilchard, with special reference to points in their digestion. Within the pyloric division of the stomach a membranous envelope incloses the food, the latter composed of the Zoëa stage of crustaceans. What peculiar function the sausage-shaped nerves serves in the economy of digestion is uncertain.—Mr. R. J. Lynch exhibited and read a short note on the contrivance for self-fertilisation in *Roscoea purpurea*, which to some extent resembles that of *Salvia* by modifications of anther and filament.—Sir John Lubbock, Bart., then read his ninth communication on the habits of ants, bees, and wasps. He detailed experiments proving that bees prefer blue flowers to those of other colours. But again if bees have so much to do with the origin of flowers, how is it there should be so comparatively few blue ones? Sir John suggests that all flowers were originally green, and then passed through white or yellow, and generally red, before becoming blue. Ants, he stated, may live seven or eight years.—Mr. C. B. Clarke described a Hampshire orchis not represented in English botany. This pale, flesh-coloured, or yellow orchis he demonstrates is the true *O. incarnata*, Linn., and not that figured by Syme and Babington, which is the *O. latifolia*, Linn.—Prof. Cobbold described a new entozoon from the ostrich, named by him *Strongylus Douglasii*. It is said to prove de-

structive to ostrich chicks at Grahamstown and elsewhere in South Africa. The worm somewhat resembles certain free nematodes, and bears few eggs.

Mathematical Society, November 10.—S. Roberts, F.R.S., president, in the chair.—At this, the annual meeting, the treasurer read his report, from which it appeared that the Society was in a very flourishing condition. The following gentlemen were elected on the council of the present session:—President—S. Roberts, F.R.S. Vice-presidents—Dr. Hirst, F.R.S., and J. W. L. Glaisher, F.R.S. Treasurer—C. W. Merrifield, F.R.S. Hon. Secretaries—Messrs. M. Jenkins and R. Tucker. Other members—Prof. Cayley, F.R.S., Sir J. Cockle, F.R.S., H. Hart, Prof. Henrici, F.R.S., A. B. Kempe, F.R.S., Prof. Rowe, R. F. Scott, Prof. H. Smith, F.R.S., H. W. Lloyd Tanner, and J. J. Walker. Mr. W. W. R. Ball, Fellow of Trinity College, Cambridge, and the Rev. G. Pirie, Professor of Mathematics in the University of Aberdeen, were elected Members of the Society. The following communications were made:—Note on the limit to the number of different proper fractions whose denominators are less than x, where x is large, by Messrs. Jenkins and Merrifield, F.R.S.—On the oscillations of a viscous spheroid, by Prof. H. Lamb, Adelaide.—A geometrical representation of a system of two binary cubics and their associated forms, by W. R. W. Roberts.—On the infinitesimal bending of surfaces of revolution, by Lord Rayleigh, F.R.S.—On tangents to a cubic forming a pencil in involution, by R. A. Roberts.—Note on Landen's theorem, by Prof. Cayley, F.R.S.

Chemical Society, November 17.—Dr. Gilbert, F.R.S., in the chair.—It was announced that a ballot for the election of Fellows would take place at the next meeting, December 1.—The following papers were read:—Aluminium alcohols, Part II. Their products of decomposition by heat, by J. H. Gladstone and A. Tribe. The authors have studied the bodies formed when aluminic ethylate, aluminic phenylate, aluminic paracresylate, aluminic thymolate, aluminium, α naphthylate, and aluminium β naphthylate are decomposed by heat. The C_nH_{2n+1} series yields the corresponding ethers, alcohols, and olefines, the C_nH_{2n-7} series yields the corresponding ethers and alcohols, together with some new crystalline bodies which are probably ketones.—On the chemical action of decomposing vegetable matter on the rock-forming sediment of the Carboniferous period, by E. Wethered. The author points out that the rocks immediately overlying the coal are in nearly all cases argillaceous, and that in the few cases where arenaceous rocks occupy that position they have a well-marked tendency to become more argillaceous as they come into contact with the coal. He proves by analysis that the chief difference in chemical composition between the two rocks is that the argillaceous rocks contain much more alumina, and concludes that this difference in chemical composition is due to the carbonic acid evolved by the decaying vegetation, decomposing all the silicates but that of alumina.—On α and β amylam, by C. O'Sullivan. The author has exhausted various grains, barley, wheat, rye, &c., with alcohol. The residue was then treated for some time with water at 40°, and the process repeated until nothing further was dissolved. The solution was filtered, evaporated, and precipitated with alcohol. The precipitate consisted of α and β amylam. These bodies were very carefully purified; the latter is soluble in cold, the first only in hot water. They have the composition of starch, but furnish apparently dextrose at once when treated with acid, without the previous formation of dextrin or any other substance. Their optical and chemical properties are fully given in the paper.—On the action of oxides on salts, Part IV. Potassic chlorate and ferric oxide, by E. J. Mills and G. Donald. The authors conclude that the action of ferric oxide on potassic chlorate resembles its action on potassic carbonate to a certain extent, that the chemical change has nothing abnormal or peculiar in its features, and that the name catalysis ceases to have any reason for its existence.—On the steeping of barley, by E. J. Mills and J. Pettigrew. The authors have compared the effects produced by steeping barley in water, and in water containing gypsum and calcium carbonate. The general effect of a calcium solution is to retain the nitrogenous matter in the grain, but to increase the total amount of extract. They attribute the value of the Burton water to the nitrates which it contains, and the consequent stimulating effects it produces in germination.

Zoological Society, November 15.—Prof. W. H. Flower, F.R.S., president, in the chair.—Prof. Newton, F.R.S., exhibited a specimen of *Emberiza rustica* recently shot on the coast of Yorkshire.—The Rev. Canon Tristram exhibited and made remarks upon skins of a darter and a pigmy cormorant procured in June of this year on the Lake of Antioch.—Mr. Sclater exhibited a specimen of the glossy ibis (*Plegadis falcinellus*) belonging to Sir Henry Mildmay, Bart., which had been shot in Hampshire in September last.—A communication was read from MM. L. Taczanowski et J. Stolzmann on the habits and various plumages of the rare humming-bird, *Loddigesia mirabilis*.—Communications were read from M. L. Taczanowski, C.M.Z.S., on two nearly allied species of humming-birds of the genus *Steganura* from Peru, and on a new species of *Mustela* from North-eastern Peru, which he proposed to call *Mustela Stolzmanni*.—Mr. W. A. Forbes read notes on the structure of the palate in the trogons (*Trogonidæ*), and on the systematic position of *Eupetes macrocercus*.—A communication was read from Mr. E. P. Ramsay, C.M.Z.S., containing an account of the true habitat of *Pycnoptilus floccosus*, Gould.—A communication was read from Mr. E. L. Layard, F.Z.S., containing a note on the South African mollusk, *Cœliaxis Layardi*, of Angas.—A communication was read from Mr. Edgar A. Smith, F.Z.S., containing notes on the shells of the genus *Chilina*, with a list of the known species.—Mr. Arthur G. Butler, F.Z.S., read a paper on some butterflies from Japan, with which were incorporated notes and descriptions of new species by Montague Fenton.—Mr. H. J. Elwes, F.Z.S, read a paper on the butterflies of Amoorland, Japan, and Northern China.

Physical Society, November 12.—Prof. Fuller, vice-president, in the chair.—Mr. W. D. Niven was elected a Member.—Mr. Lewis Wright then read a paper on some spirals observed in crystals, illustrating the relation of their optic axes. After remarking that the relation of the axes in uni-axial and bi-axial crystals had always been an interesting subject, he observed that if we took any uni-axial and a single axis of any bi-axial which had little or no axial dispersion, and polarised and analysed each circularly, we ultimately got similar phenomena. This is illustrated by calcite and a single axis of sugar, each giving, when thus treated, unbroken circular rings. From this it might be hastily inferred that a single axis of a bi-axial resembled in character the axis of a uni-axial, but this was not the view of those who framed the theory of double refraction in crystals. Fresnel finally framed the conception of three elasticities in three rectangular directions. If all were equal, there was no double refraction; if only two were equal, there was a single optic axis in the direction of the third; and if all were unequal, there were two optic axes. According to this theory the axis of the calcite did *not* resemble in character a single axis of the sugar or other bi-axial, but was a limiting case in which *both* such axes coincided. This was illustrated by the beautiful experiment of Prof. Mitscherlich applying heat to a crystal of selenite, and thereby altering the respective elasticities. The two axes gradually approached until they coincided and the crystal became uni-axial, after which, on heating the crystal still more, the axes re-opened in a direction at right angles to the former, thus proving Fresnel's theory. A point still to be illustrated was that the axis of a uniaxial did retain, or still embraced within itself in some visible form, characteristics of the two axes thus brought into coincidence. Sir George Airy had discovered the double spiral in quartz. Uniaxial calcite showed a double spiral; and biaxials gave a single spiral. Mr. Wright repeated Prof. Mitscherlich's experiment, with Airy's additional method of analysis; the spirals being first shown perpendicularly arranged above each other. Gradually they approached until they resembled those of the calcite, and finally opened out again horizontally. All through there was a double spiral, and a single one could only be got by separating a single axis. The axis of a uniaxial always preserved what might be called its "twin" or "double" character. This experiment was the ocular demonstration sought that the axis of a uniaxial, as a limiting case, did contain or retain elements capable of being made visible. It further showed the reason of the double spiral discovered by Sir George Airy in quartz. This crystal evidently was able to show its own spirals, which, of course, are double. It was shown that as the convergence of the rings was increased these spirals became as numerous and definite as in the calcite. There was however a crucial test of this view: for if it were correct we could combine the two properties of the quartz, artificially as it were, since many fluids also possess rotary power. If therefore we took a column of such fluid of sufficient length and an ordinary uniaxial crystal, the fluid would represent the axial proper-

ties of the quartz, and the crystal the other properties, and the two ought to give similar spirals. In fact the fluid should replace the quartz successfully in all these experiments. By means of a column of oil of lemons 200 millimetres in length, and crystals of calcite, sugar, topaz, and nitre, Mr. Wright showed this to be the case. Finally he demonstrated that the same phenomena held good through all the ordinary analogies with, or artificial substitutes for, natural crystals, the figures being produced with a circular chilled glass in parallel light, and also with an artificial uni-axial crystal made of crossed mica films, after Norremberg, and an artificial quartz made of superimposed mica films, after Reusch, in convergent light. All the figures were projected by the electric camera to a size 8 feet in diameter. All Mr. Wright's experiments went to illustrate the truth of Fresnel's theory.—Mr. C. V. Boys then read a paper on the prevention of the bursting of water pipes. Mr. Powell had proposed the use of pipes of elliptical or other round section, and Mr. Mangnal of Manchester had independently hit on the same idea. Such a pipe would become rounder in section when the water froze and expanded. A round pipe tends to become thinner at its weak parts on expanding under the pressure. With an elliptical pipe, the force required to alter the shape of its section is greater as the section is more circular, therefore the effect produced by a change of shape at any place makes that place stronger. A round pipe is in a state of unstable, and an elliptical pipe in a state of stable, equilibrium, and changes its form uniformly from end to end. Hence if a portion only of such a pipe is exposed to the cold, the whole is effective, and it will require a proportionally greater number of frosts to make the pipe round. Inspection would show if the pipes were becoming round, and then they could be squeezed back to their original shape. Mr. Boys had demonstrated these inferences by experiment with Mr. Powell. Messrs. Powell, Rigby, and Co. of Piccadilly made these pipes.—Mr. J. Macfarlane Gray drew attention to some apparent discrepancies in the constants employed by Regnault in his work on "The Physical Properties of Steam."

PARIS

Academy of Sciences, November 14.—M. Wurtz in the chair.—The following papers were read:—Researches on electrolysis (continued), by M. Berthelot. He illustrates the "principle of minimum electromotive force in electrolyses," in virtue of which electrolytic decomposition occurs as soon as the sum of energies necessary is present. It is distinctly verified wherever there is no polarisation of electrodes.—The maritime laboratories of Banyuls-sur-Mer and Roscoff, by M. de Lacaze-Duthiers. The Roscoff station has had increasing success: 38 have worked at it this year, as against 27 in 1880 (there are 25 at present). The number of foreigners is eight. A large fish-pond has been added, and Government has provided a vessel for dredging. Banyuls-sur-Mer was fixed on for a winter station. The author gives particulars of what is to be called the *Arago Laboratory*, &c., which will be ready early next year. He has received 48,000 francs. The Mayor of Banyuls has opened a subscription for a dredging vessel.—Observations on the second volume of M. Fontaine's Universal History; the Iranians, by M. de Lesseps.—On the working zone of anæsthetic agents, and on a new process of chloroformisation, by M. Bert. With increasingly-strong mixtures of an anæsthetic vapour and air, a point is reached at which an animal in such an atmosphere is made insensible, and another point at which it is killed. The interval between these is the *zone maniable*, or working zone. M. Bert used chloroform, ether, amylene, bromide and chloride of ethyl, and the animals were dogs, mice, and sparrows. Under these conditions the fatal dose is precisely double the anæsthetic dose. (In the case of protoxide of nitrogen the ratio is one to three.) The zone is much greater for ether than for chloroform. Animals anæsthetised in the way indicated remain perfectly quiet and need no attention. In the common way of applying chloroform, with a compress, the limits of the working zone may be exceeded on either side. Chloroform acts, not by the quantity respired, but by the proportion in which it exists in inspired air. The author applies the mixture through a tube and a small mask. The anæsthetic dose for man has yet to be determined.—Synthesis of azotised colloids, by M. Grimaux. Proteic matters he defines as azotised colloids breaking up, through hydration, into amic acids, carbonic acid and ammonia, and from this his method of synthesis is derived. He combined aspartic anhydride with urea.—Crystallographic observations on a variety of natural blende, by M. Hautefeuille.—Observations of Schäberle's comet (*c* 1881) at Rio Janeiro Observatory, by M. Cruls.—On the theory of motion of celestial bodies, by M. Callandreau.—On certain series for development of the functions of a variable, by M. Halphen.—Equality of mean sinking produced by two equal loads (each at points where the other is deposited) arbitrarily distributed along two concentric surfaces on a horizontal ground, or on a horizontal circular plate having the same centre as these circumferences, and supported or secured throughout its contour, by M. Boussinesq.—On the maximum yield of which two given dynamo-electric machines are capable, when used for transport of force, by M. Lévy.—Researches on the absorption spectrum of our atmosphere at Paris Observatory, by M. Egoroff. He describes the absorption of strong electric light by the air-layer between Mont Valérien and the Observatory, observed on eleven evenings. It is probable that, after aqueous vapour, air is the only strongly absorbent substance.—On the electrolysis of water (continued), by M. Tommasi. All metals except gold and platinum, being able to combine with the oxygen of water under action of the voltaic current, are capable, when positive electrodes, of decomposing water by action of a single (zinc copper or zinc carbon) element. He here shows that the decomposition will occur if one of the two electrodes is aluminium, zinc, or carbon. He opposes some of M. Berthelot's views.—On the reversibility of the electro-chemical method for determination of systems of equipotential or discharge, by M. Guébhard.—On the magnetic properties of the nickelised iron of Santa Cattarina, Brazil, by M. H. Becquerel. There is great increase of magnetism after heating followed by cooling, and the author got a like result with pure nickel crystallised in the cold state; but not with pure iron. The native iron must have crystallised at a low temperature.—On the proportions of carbonic acid in the high regions of the atmosphere, by MM. Müntz and Aubin. The observations, made on the Pic du Midi (2877 m.) gave 2·86, which is extremely like the figure got on the plain of Vincennes, and similar figures were got in two Pyrenæan valleys.—On the post-embryonal development of Diptera, by M. Viallanes.—The pourridium of vines of Haute-Marne, produced by *Ræsteria hypogæa*, by M. Prillieux.—Bauxites, their age and origin; complete diffusion of titanium and vanadium in rocks of primordial formation, by M. Dieulafait.

VIENNA

Imperial Academy of Sciences, November 3.—L. T. Fitzinger in the chair.—The following papers were read:—A. D'Albert Adamkiewicz, on the blood-vessels of the spinal cord of man, Part II. The vessels of the spinal marrow.—E. Heinricher, contributions to the teratology of plants.—E. Tangl, on nucleus and cell division in the formation of pollen of *Hemerocallis fulva*, L.

THURSDAY, DECEMBER 1, 1881

THE ACCIDENTS IN MINES COMMISSION

THE Preliminary Report of this Commission, recently issued, affords a rather striking illustration of the amount of unpaid work which is occasionally done for the public by our busiest men. The Commission was appointed to inquire whether "the resources of science furnish any practicable expedients not now in use which are calculated to prevent the occurrence of accidents in mines or limit their disastrous effects." In its constitution science was represented by the following Fellows of the Royal Society:—Mr. Warington Smyth, Prof. Abel, Prof. Clifton, and Dr. Tyndall. The employers were represented by Sir George Elliot, M.P., Mr. William Thomas Lewis, and Mr. Lindsay Wood; the employed by the Member for Morpeth, Mr. Burt. Earl Crawford (then Lord Lindsay), who was added by a subsequent Royal Warrant, combined the man of science and the employer. He is a Vice-President of the Royal Society, and is largely interested in mining industry. Mr. Warington Smyth was very properly selected by the Home Secretary to preside over the Commission, for his scientific attainments are supplemented by varied and accurate knowledge of practical mining

The Commissioners set about their work in the most thorough manner. "In order to ascertain in what direction they could most usefully prosecute their inquiry," they "obtained the best possible evidence on the circumstances under which mines are worked, and on the acknowledged or probable causes of accident." They examined all the inspectors of mines, a large number of experienced colliery viewers and mining engineers, and a number of workmen selected by the miners' associations. They visited and inspected collieries in all parts of the kingdom, including most of those in which explosions of serious magnitude have recently occurred. At an early stage of their inquiry they found that they must make a series of extensive experiments, "involving much time and labour." They did not hesitate, they say, to "enter upon these experimental researches," and "there is good reason to hope," they add, "that their prosecution will result in the development, and perhaps in the settlement of, important questions bearing upon the elimination of accidents in mines."

In the meantime, as these experimental inquiries must necessarily take some time, they have thought it best to present at once the evidence which has been taken by them.

This evidence is preceded by a very interesting summary: One of the most important facts to which they draw attention is the great improvement which, so far as safety is concerned, has taken place during the last thirty years. Whilst the total number of deaths remains almost the same, the number of persons employed has nearly doubled, so that the fatalities have been reduced by nearly one-half.

These satisfactory results—as they point out in detail—are due to the scientific treatment of the various problems involved in underground operations, and to the increased care and regularity exercised generally by workmen and officials in the daily routine of their work.

The body of evidence which they have presented is full of interest and importance to all who are concerned in this great branch of our industry, whether as colliery owners, officials, or workmen. It has evidently satisfied the Commissioners as to the direction in which they must prosecute their inquiry, and as to the scientific problems which still remain to be solved. The source of danger which has hitherto defied all the efforts of science is the existence of light carburetted hydrogen gas—popularly known as "fire-damp"—in the coal. Falls of roof and side cause more than half the fatal accidents in mines. But a fall of roof never exacts more than one or two victims, and attracts scarcely any attention. The issue of fire-damp from the coal may—and often does—destroy hundreds of lives at a time, with a sudden, swift, and awful explosion, which strikes a natural terror into the whole mining population.

Wonderful as have been the recent improvements in ventilation, which are described in this Blue Book, the enormous volumes of air obtained by the best constructed furnaces or the most gigantic fans are unable to cope with the "sudden outbursts" of gas, which appear to increase in number as the deeper measures are reached. Recent experiments made by one of the Commissioners—Prof. Abel, at the request of the Home Office, and described in the summary—have revealed another danger, which improved ventilation may, under some circumstances, increase rather than diminish. From these experiments it appears that the presence of coal dust in the air of a mine renders it explosive if the air contains a proportion of fire-damp so small that it cannot be detected by the most experienced observer with the means at present in use. Here it is that the Commissioners appear to consider that patient research and experiment may be of some avail. Fire-damp is harmless unless it be ignited. The only two ways in which it needs be ignited are by the lights used for lighting the mine and by the explosives used for driving headings and bringing down the coal. If a method of lighting could be devised which would not ignite an explosive mixture of fire-damp, all danger in that direction would be removed. If an explosive or other equally efficacious agent were devised which would not ignite such an explosive mixture, all danger in that direction would be removed. The Commissioners have had the electric light introduced experimentally at the Pleasley Colliery, near Mansfield. But though they say that an admirable illumination was obtained with Swan's electric lamps, they add that "further experiments and a full examination into all details connected with its application are needed before it can be decided whether the electrical illumination of workings is practically achievable."

With reference to the existing system of lighting by safety lamps, the Commissioners afford another instance of laborious inquiry. They found a powerful blower of natural gas at Mr. Smethurst's Garswood Hall Colliery, near Wigan. Here they had suitable apparatus put up, and made several hundreds of careful experiments with about fifty varieties of safety lamps, for the purpose of determining the relative safety of each variety. Not satisfied with those, they say it will be desirable "to carry on these experiments in further detail, and to repeat them in other localities with other varieties of fire-damp." We understand that the Commissioners have nearly completed

arrangements for continuing these experiments at the Llwynpia Colliery of the Glamorgan Coal Company, where there is a large blower of natural gas.

On the subject of the other source of danger they make the following observations:—"The use of gunpowder and other explosives is at the present day so widely spread, and is held by many to be so indispensable, that all suggestions for checking their application in certain cases on account of risk need to be very carefully weighed." "An overwhelming majority of our witnesses assert that it is practically impossible, as a rule, to work mines without powder." They conclude however a review of the evidence on this subject with the following rather significant statement:—"In the meanwhile it has appeared to us to be desirable to make trials of such methods of 'falling' or bringing down the coal as may do away with the danger caused by sparks and flame; and with this view a series of experiments already commenced will be continued in different localities"

The result of these further inquiries and experiments with reference to lighting and blasting, it is of course impossible to forecast. We fear it would be rash even to hope for an announcement that for the future fiery seams may be worked with a light, and brought down by an explosive, neither of which can ignite an explosive mixture, and both of which can be readily adopted without adding to the cost of getting the coal. But we await with much interest the conclusion of an inquiry which has been conducted in such a thoroughly scientific manner, and upon which so much practical experience, time, and labour have been bestowed.

CELESTIAL OBJECTS FOR COMMON TELESCOPES

Celestial Objects for Common Telescopes. By the Rev. T. W. Webb, M.A., F.R.A.S. Fourth Edition, revised and greatly enlarged. (London: Longmans, Green, and Co., 1881.)

THIS is a new and much extended edition of a work which has attained considerable popularity amongst the many amateurs of astronomy in this country who are limited to the use of instruments of moderate optical capacity, or as the author terms them, "Common Telescopes." By this term are intended achromatics with aperture of from three to five inches, or reflectors of somewhat greater diameter, yet as telescopes of higher pretensions are now in the possession of private observers, the author in the selection of additional objects has aimed at including such as may be considered tests for a superior class of instrument. The increase in telescopic range applying chiefly to the sidereal branch of astronomy, the additions have been taken for the most part from the works of the Struves and Burnham for double stars, and Sir John Herschel's catalogue for nebulæ: the total increase in the number of objects brought together in this new edition over the preceding one, is stated to be about 1500.

The first part of the work relates to the solar system, with a popular account of the actual state of our knowledge of the characteristics of its various members, so far as they fall within reach of moderate telescopes. In treating of the sun, the author collects many cases of the observation of dark spots in motion upon the disk, including that recorded by Mr. Capel Lofft of Ipswich, in January, 1818, to which, if we mistake not, attention was first specially directed by Mr. Webb in an earlier edition of the present work. He reproduces Pastorff's drawings of what he supposed to be the great comet of 1819, in transit across the sun, on June 26, taken from the originals, which are in the possession of the Royal Astronomical Society. The *phosphorescence of the dark side* of Venus, a phenomenon not as yet satisfactorily explained, is dwelt upon, as also the problematical satellite assigned to this planet. The moon is the subject of detailed description, the peculiarities of her surface, and the various craters, walled plains, valleys, clefts or rills, annular mountains, &c., are brought together in an interesting form; a map of the lunar surface forms the frontispiece to the volume, and a full index to the five hundred spots marked upon it, with an "Alphabetical Table of Lunar Nomenclature," is amongst the contents: indeed our satellite forms the subject of special treatment, which is amongst the most notable and useful features of Mr. Webb's work. An outline chart of the surface of Mars follows, with the actual nomenclature, which we hope at no distant time to see placed upon a more satisfactory foundation. The principal points of interest furnished by telescopic observation of the disks of Jupiter and Saturn are referred to, though, from the limited space at disposal, in less detail than the reader might perhaps desire. Cases of visibility of the brighter satellites of Uranus, and the satellite of Neptune, with telescopes of moderate dimensions, are recorded.

After a brief notice of comets, the author passes to the main division of his work—sidereal astronomy, or, as he phrases it, "The Starry Heavens,—Double Stars, Clusters, and Nebulæ." In this division, as it appears to us, Mr. Webb is at a disadvantage in being compelled to employ a system of abbreviation which, in the eyes of some readers, will not be without its disadvantage: but he has been perfectly aware of this, and in his Introduction asks the reader "to excuse a condensed form of expression, the result of necessity rather than of choice"; the amateur who intends to make practical use of the work must therefore accustom himself at the outset to Mr. Webb's abbreviations, and it must be admitted that it would have been difficult, without some such system, to have given the amount of information which is contained in the 300 pages or less, devoted to stellar astronomy. Mr. Webb follows the convenient plan of taking the constellations in alphabetical order, so far as they are visible in these latitudes: telescopic objects in the southern heavens are only noticed in a short appendix. The positions of the various objects are given to the nearest minute of time only in right ascension and the nearest minute in declination, but it may be remarked that the former is not a sufficiently close indication of the places of several interesting objects which fall well within the scope of observation of many amateurs, whom it might be desirable to enlist for their more systematic observation. We allude to cases like that of Tycho Brahe's star of 1572, Kepler's star of 1604, or Anthelm's in 1670. For the former the author gives R.A. 0h. 19m., Decl. 63° 24′ N., and recommends that a minute star near the place should be watched; but any one acquainted with the neighbourhood will know that a

closer indication of its place is necessary for the identification of the suspicious object: it is the same with the small stars near the positions of Kepler's and Anthelm's stars. Variability has been remarked in small stars which occupy places very close to the observed positions of Tycho's and Anthelm's stars, and probably also in the case of Kepler's, and it is very desirable that a strict scrutiny of these spots should be maintained. As happens in so many popular treatises, there is a confusion in Mr. Webb's statement with regard to Kirch's variable star χ Cygni (Bayer): the Greek letter is attached at p. 288 to the double star No. 2580 of Struve, and it is added, "About $4^m f$, 50's is 17, or χ Bayer, discovered by Kirch; 1686, to be var., sometimes up to 5m.," &c. It is, however, Flamsteed's 17 Cygni which corresponds to Struve's double-star, while the variable star is χ Cygni of Bayer. Flamsteed, it is true, attached the letter χ to his 17 Cygni, though, as was pointed out by Argelander many years since, through a mistake: he saw no other sufficiently bright star near the place to correspond to Bayer's, but the explanation of this circumstance is found in the fact that at the dates of Flamsteed's observations "the variable star was down," to borrow an expression with which observers of these objects will be familiar, so Flamsteed seized upon the nearest naked-eye star for Bayer's χ. Mr. Webb dwells particularly upon the colours of the double-stars, one of their most interesting characteristics, and has brought together a large number of attractive notes upon the objects which he includes in his survey of the northern heavens. That his volume will maintain its popularity amongst amateur astronomers is not to be doubted, and we must add that it well deserves to do so.

CARNAC

Excavations at Carnac. By James Miln. (Edinburgh: Douglas, 1881.)

MR. MILN, to whom we are already indebted for a work on Roman remains found near Carnac (Britanny), has continued his researches in this interesting locality, and has given us a second work, consisting of a record of archæological researches in the alignments or stone avenues of Kermario.

The alignments of Kermario consist of ten rows of undressed stones, which extend for about two miles in an easterly direction, after which begin the avenues of Kerlescant. The stones, which consist of a close-grained granite, are some of them as much as twenty feet high, though the majority are much smaller. At the base of many of them Mr. Miln found ashes, charcoal, and fragments of pottery of a character which led him to the conclusion that these mysterious and almost unique avenues of stones were erected as sepulchral monuments. Although the whole monument is of such an extensive character, Mr. Miln is of opinion that it had not been completed. He draws this inference from the fact that in the neighbourhood he found several heaps of long stones, which he supposes had been brought there in order to be erected.

Among the stone avenues run certain ancient earthworks, and at the head of them are, as Mr. Miln found, the remains of ancient buildings. It was in these earthworks, at the base of the menhirs (which however he was very careful not to overturn), and among the ruins of these buildings that Mr. Miln's excavations were carried on.

The principal interest of the objects discovered in his researches, is the evidence they afford as to the period at which these menhirs were erected, and Mr. Miln comes to the conclusion from the result of his investigations that between Kermario and Kerloquet we have a long stretch of defensive works erected by the Celts at a period anterior to the Roman invasion; that the Romans on their arrival had occupied some of these, and in the more advantageous positions had constructed other works of greater solidity. On the other hand there seems some evidence that the erection of standing stones or menhirs did not altogether cease at this period, for under some of them, and in positions which would seem to show clearly that they were placed there at the time the menhirs were erected, fragments of Roman tiles and pottery have been discovered. These menhirs, however, formed no part of the "alignments."

It is interesting that, as Dr. Closmadeuc had already pointed out, we have evidence that there has been a change in the level of the land since the erection of these monuments. Mr. Miln considers that nearly the whole, if not the whole, of the bay of Quiberon must then have been dry land. On the Quiberon side of the bay the rows of menhirs extend under water, and on the Carnac side too, Gallo-Roman potters' furnaces have been found below high-water mark.

We much regret to add that the author died the very day after he had finished the proof sheets of this work. The present writer had the pleasure of examining Mr. Miln's excavations with him in the autumn of 1877, and may be permitted to add his personal expression of regret at the loss which archæological science has experienced in his death.

OUR BOOK SHELF

The Mind of Mencius. By the Rev. E. Faber. Translated by the Rev. A. B. Hutchinson. (Trübner's Oriental Series. 1881.)

MR. FABER is already well known in the field of Chinese studies by his digest of the doctrines of Confucius. In the present volume he gives us a systematic digest of those of Mencius, the greatest and most popular of the disciples of Confucius. These two philosophers form the bulwarks of Chinese conservatism, against the doctrines of socialism and communism, which first thrust themselves into notice after the death of Confucius. These men, as the translator remarks, made no appeal to external credentials; they rather based the truth of their mission on the conformity of their doctrines with the essentials of the human mind, as shown by observation. To them the "state" is everything—it is "the sum of all human endeavours, natural and civilised, working together as a united organisation." For about 3000 years the political fabric of China, based on the principles of which Confucius and his disciples were the exponents rather than originators, has held together in spite of shocks before which any other system known in history would have disappeared, and at the present day seems as vital and vigorous as at any portion of its existence. To explain by the light of the best commentators what these principles, as enunciated by Mencius were, is the object of Mr. Faber. This philosopher was a contemporary of Plato and Aristotle, but his doctrines are still living and active principles in Chinese ethics and politics. The

value of this work will be perceived when it is remembered that at no time since relations commenced between China and the West has the former been so powerful—we had almost said aggressive—as now. She is drawing closer to us as time goes on, but there is no evidence that the tenacity of her hold on her ancient political doctrines is relaxing. For those who will give it careful study Mr. Faber's work is one of the most valuable of the excellent series to which it belongs.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Primitive Traditions as to the Pleiades

In Dr. Tylor's recent review in NATURE (vol. xxiv. p. 529) of Mr. Dawson's work on the "Folk-Lore of the Natives of Victoria," he refers to their tradition of "the lost Pleiad," and assumes that it must have been borrowed by them from Europeans. The indefatigable Astronomer Royal for Scotland, conceiving that my researches as to the Pleiades, and especially as to traditions respecting those stars among the Australians, had been improperly ignored, wrote a letter to the Editor of NATURE, which, having been submitted to Dr. Tylor, was sent to my Canadian address, with his reply, by Prof. Piazzi Smyth, and has only reached me within the past week.

Dr. Tylor states that he has frequently heard of my researches respecting the Pleiades, but has never met with any publication of mine on the subject; and that he would be much surprised if I could show that the story of the "Lost Pleiad" is really a primitive and original myth of savages.

Before touching on that point I think it but right to say that, so far from feeling aggrieved by the omission, I am afraid that I rather owe an apology to Dr. Tylor and to anthropologists for not having long ago published the results of my labours.

If a paper on the subject would have been only read and used by Tylors and F.R.S.s, I should long ago have given them the substance of the fruits of my investigations. Unfortunately there are scores of imaginative persons who have a fondness for discussing scientific novelties, without having the caution and training necessary for such work. Hence the unfortunate discoverer or explorer of any new and difficult field of research is apt to find that, long before he feels justified in inviting the attention of the scientific world to his favourite subject, it has been invaded and discredited by hasty theorists; and that his first work is the unpleasant task of clearing the field of the rubbish with which it has been encumbered.

Now there are few subjects as to which greater caution is needed than that of anthropology, and especially that branch which deals with the myths and religious ideas of savages. Dr. Tylor's works are therefore very satisfactory, as they contain a vast mass of facts, and evince an entire absence of fanciful or hasty theories. Had I confined my researches to the study of the folk-lore of savages I should never have supposed that the Pleiades deserve the prominence which my conclusions have assigned to them.

As my researches are unknown to most persons, and only imperfectly known to a few through my privately printed journals of investigations, letters, &c., having been partially published by others, permit me to explain the course of my investigations, and the grounds for my conclusions as to the Pleiades and their influence on the calendars and mythologies of nations.

It is now almost a lifetime, some thirty years ago, since I first noticed the universality of the number *seven* on ancient symbolism. As seven stars frequently met me as an architectural symbol, or a religious emblem in the New World, as well as in the Old, sometimes too in connection with the prehistoric cross, I suspected that these stars must have been the Pleiades, and that they must have in some way consecrated that symbol and the number *seven*, a number, too, which I had noticed as being prominent in the grouping of some prehistoric structures. Why such apparently unimportant stars should have once acquired such world-wide significance I was utterly unable even to offer a conjecture.

After corresponding with Mr. Prescott, Sir Austin Layard, and others on this subject, I made up my mind that I had got hold of the wrong end of a very important inquiry, and that for years to come I must carefully collect facts and religiously avoid hasty generalisation.

On subsequently paying my first visit to England the late Sir Henry Ellis, the editor of "Brand's Popular Antiquities," requested me to prepare a paper on the coincidences of customs among savages and civilised nations, and I accordingly selected those connected with the Feast of Ancestors, as I found that my references and notes on it were very numerous.

I had previously noticed that a Spanish Jesuit missionary had expressed surprise that the Peruvians and Christians observed the feast of the dead on the same day—the second of November. I of course looked on the coincidence as purely accidental, but when I had written a paper giving the results of my notes, to my great amazement I found that this coincidence was very widely spread, and that the feast of ancestors was very generally held about the beginning of November. Here then was a truth not hitherto "dreamed of in our philosophy"; and I therefore thought it prudent to defer reading my paper until I could solve the mystery.

How could this singular coincidence have been caused and preserved throughout the world, in the northern as well as in the southern hemisphere? It was plain that this festival must have been regulated by something very simple and plain, such as the rising of some star. If this was the case, then it was equally clear that that star must have been very carefully observed throughout the world, and may therefore have become an object of peculiar reverence. I at once thought of the widespread symbolism of the Seven Stars, which I had long before noticed, and therefore, as I was not an astronomer, I asked Prof. Everett, F.R.S., then a professor in King's College, Windsor, Nova Scotia, whether the Pleiades could ever have risen in November. He of course replied in the negative, for it must have been at least twelve thousand years since those stars rose heliacally at that time of the year. I had, however, my conjecture fully confirmed by finding that in one of the most ancient calendars in the world, that of the Brahmins of Tirvalore, the name of November was *Kartica* ("the month of the Pleiades"). I subsequently found a year, still in use in Polynesia, regulated by the rising of the Pleiades at sunset, or by their being visible all night long, and I also discovered that the three days' feast of the dead was also held in November by the Australian savages as a great annual corroboree in honour of the Pleiades. Since then I have found this primitive calendar, or fossil traces of it, all over the world.

I also found that early astronomers constructed great years or cycles on the basis of this simple calendar, which were also regulated by the Pleiades. With this calendar and its festivals and these cycles I found flood traditions and primitive myths associated, and that the key to some of the most remarkable features in early religions and traditions is to be found in the year of the Pleiades.

In 1863 I printed privately a paper of 103 pages on the Feast of the Dead, and the calendar of which it was a new year's festival, and in 1864 a second paper on the connection of the Pleiades with the cycles of the ancients and with prehistoric chronology.

As Prof. Piazzi Smyth, in 1865, was intending to carefully measure and examine the Great Pyramid, I sent him a copy of my papers, as I believed that my early impressions as to the connection of the Pleiades with primitive architecture would prove to be well founded. In his work on the Pyramid he republished seventy pages of my first paper, my request that it should not be published having fortunately reached him too late.

My excuse for this long delay is the desire, before publishing my conclusions, to work out many interesting problems connected with the Pleiades and early myths and religious beliefs, and the great difficulty of such inquiries; for the era when the Pleiades thus left their impress on the calendars and traditions of nations must be very remote, so much so that such researches are like investigations into the fossils that tell of organisms that lived in a world and breathed an atmosphere different from our own.

I am, however, preparing at last to bring out a work which will deal with the connection of the Pleiades, first, with the calendars, festivals, and cycles of nations; and next, with the myths and traditions associated with the year of the Pleiades. I

had recently intended to have published some articles which I had prepared on the connection of the Pleiades with primitive ideas as to Paradise, but it seemed prudent to defer doing so, and to bring out the whole subject in one volume. To show, however, how widely spread these traditions as to the Pleiades are, I may attempt to give the information which Dr. Tylor invites, as to the myth of the lost Pleiad being a heritage among savages. Those stars are only apparently six, yet all the world over, among civilised and savage races, in Europe, in India, China, Japan, America, and Africa, this diminutive star group is not merely regarded as seven stars, but what is still more surprising, as "*The* Seven Stars," though the far brighter seven stars of the Great Bear might seem to deserve the title.

There are various myths to account for the missing Pleiad, but one I think will suffice to show that the Australians did not borrow the idea from Europeans.

I once asked a native of the Gold Coast, a negro Hercules in strength, who had therefore been christened (probably by some pious naval officer) *Fivehorsepower*, whether he knew anything of the stars. "No!" he replied, "I know nuffin about de stars." "But don't you know anything of 'the seven stars'?" "Oh yes, of course," he answered; "every nigger knows de seben stars." "Why do you call them seven?" I asked him; "can you count seven stars?" "No," he replied, "you count one, two, three, four, five, six; then todder one hide herself, no let you count her." There is also a savage tradition, which I can recollect, that the Pleiades are young women, six of whom are very beautiful, but the seventh is so plain that she conceals herself from sight.

Some tribes of the Australians dance in honour of the Pleiades, because "they are very good to the black fellows." Was this borrowed through Europeans from "the sweet influences of the Pleiades" which Job celebrates?

Ask a negro in the Southern States to look through a telescope, and he will invariably turn it towards the Pleiades, "for they are berry good to the darkies." The natives of America, both North and South, regard the Pleiades as beneficent stars, and dance in their honour. "Oh what do we owe to thee!" is the grateful salutation of one tribe. Whence then did this arise? It was not merely because those stars announced spring, and were "stars of rain," or because they were "for signs, and for seasons, and days, and years," but also because they were connected with the idea of Paradise and the abode of the Deity. The problematical theory of Moedler, that Alcyone, the brightest of the Pleiades, is the central sun of the universe, is most interesting on account of the singular fact that such was actually the belief of early ages. I have within the past year found unexpected, and I think conclusive, proofs that the name *Alcyone* (or rather, *Alkyone*), meaning a centre, pivot, or turning-point, was not given without some reason to that star, for the ancients in very remote ages undoubtedly believed that it was the centre of the universe, and that Paradise, the primæval home of our race and the abode of the Deity and of the spirits of the dead, was in the Pleiades, traces of which ideas we even find among savages.

The *Alkyonic* Lake, the waters of which led to the world of spirits, must have meant simply "the waters of death" leading to Alkyone or Paradise, and reminds us of Ulysses' voyage to the abodes of the dead and to the Gardens of Alkynöos.

With the Pleiades, too, sacred birds (birds of paradise) were connected. In my journal of researches (1863) I expressed my conviction that *Manu* (a word meaning, in the Indian Archipelago, a fowl or bird) would be found to have been connected with the Pleiades. I have been recently gratified at finding that in far-distant Samoa there is a sacred bird called, not *Manu-alii*, the royal bird, as some European writers have assumed, but *Manu-lii*, the bird of the Pleiades.

What a singular link we have here between the folk-lore of these savages and that of the Old World, for to this very day, from Britain to Japan, the Pleiades are popularly known as "the hen" or "hen and her chickens."

In Mexico the beautiful kingfisher was a sacred bird. May not the name of the same bird in Greece have been a survival of similar ideas, as it was called the *Halcyon, i.e.* belonging to Alcyone, or a bird of paradise?

The bright sunny days, too, at the end of autumn, that shining season of the Pleiades, called in America the Indian summer, were *Halcyon* days among the Greeks, which we should now render heavenly days.

Even if the theory of prehistoric astronomers and of some modern men of science, that the Pleiades are the centre of the universe, should prove to have been unfounded, I am persuaded that the day is coming when the learned will admit that those stars are the "central sun" of the religions, calendars, myths, traditions, and symbolism of early ages—an era, however, so marvellously remote, that investigations respecting it bear the same relation to the study of anthropology and to the science of religion that palæontology does to natural history.

I shall be greatly disappointed if I cannot satisfy even so cautious and careful an observer as Dr. Tylor, that there is a mass of original and primitive traditions as to the Pleiades among isolated savages in various quarters of the globe.

In the meantime, until these conclusions are submitted in a proper and scientific shape to the learned, Dr. Tylor is perfectly justified in adopting the prudent legal maxim, *De non apparentibus et non existentibus eadem est ratio.*

I may however invite his attention to Mr. Ernest de Bunsen's recent work on the Pleiades—"The Pleiades and the Zodiac," published in German (Berlin, 1879), and his recent learned work, the "Angel Messiah." The former he has kindly dedicated to me as the pioneer in this new and difficult field of research.

R. G. Haliburton

The Pronunciation of Deaf-mutes who have been Taught to Articulate

In Nature (vol. xxv. p. 72) it is reported that at the last meeting of the French Academy M. Hément made some observations to show that deaf-mutes who have been taught to articulate speak with the accent of their native district. This curious circumstance, which was contested by M. Blanchard, has already been recorded. One case is given in an old number of the *Philosophical Transactions*, No. 312. About the age of seventeen a young man, a congenital deaf-mute, was twice attacked by fever. "Some weeks after recovery he perceived a motion of some kind in his brain, which was very uneasy to him, and afterwards he began to hear, and, in process of time, to understand speech. This naturally disposed him to imitate what he heard, and to attempt to speak. The servants were much annoyed to hear him. He was not distinctly understood, however, for some weeks; but is now understood tolerably well. But what is singular is that he retains the Highland accent, just as Highlanders do who are advanced to his age before they begin to learn the English tongue. He cannot speak any Erse or Irish, for it was in the Lowlands he first heard and spoke." The curious circumstance of his possession of the Highland accent is confirmed by the testimony of similar phenomena in the deaf and dumb schools of Spain. "One fact," says Ticknor, "I witnessed, and knew therefore personally, which is extremely curious. Not one of the pupils, of course, can ever have heard a human sound, and all their knowledge and practice in speaking must come from their imitation of the visible mechanical movement of the lips and other organs of enunciation by their teachers, who were all Castilians, yet each speaks clearly and decidedly, and with the accent of the province from which he comes, so that I could instantly distinguish the Catalonians and Biscayans and Castilians, whilst others, more practised in Spanish, felt the Malagan and Andalusian tones" ("Life and Journals of George of Ticknor," vol. i. p. 196, London, 1876). A similar case has been mentioned to me by Mr. J. J. Alley of Manchester. E. R. became deaf and dumb at a very early age, and did not talk until he was about seventeen, when he was taught articulation by Mr. Alley. He speaks with the accent of his native county of Stafford. These facts are cited in my paper on "The Education of the Deaf and Dumb," in the "Companion to the Almanac" for 1880.

William E. A. Axon

Tanganyika Shells

In the *Proc.* Zool. Soc. Lond. for May, 1881, pp. 558–561 Mr. Edgar A. Smith has described two new species of shell from Lake Tanganyika, Africa, for which he has proposed the new generic name of *Paramelania*. These forms are, without doubt, generically identical with the *Pyrgulifera humerosa* of Meek (see U.S. Geol. Sur. 40th Parallel, by Clarence King, vol. iv. p. 176, pl. xvii. Figs. 19 and 19*a*), which antedates Mr. Smith's name by at least five years. Mr. Meek's species has hitherto been the only known member of the genus, either fossil or recent, and was only known to occur in the strata of the

Laramie group, an extensive brackish water formation in Western North America, which holds a transitional position between the Mesozoic and Cenozoic series. Associated with *Pyrgulifera humerosa*, among various other fresh and brackish-water forms, is one that I have described under the name of *Goniobasis cleburni*, which is evidently congeneric with the *Melania* (*Sermyla*) *admirabilis* of Smith, an associate of *Pyrgulifera damoni* and *P. crassigranulata* in Lake Tanganyika. As that lake has evidently once been a brackish water sea, it is not strange that there should be certain similarities between its molluscan fauna and the faunæ of similar bodies of water that existed in Mesozoic and Cenozoic time. It is, however, remarkable that the two generic types here especially referred to should appear in their integrity living in Africa, and not in North America, where the fossil forms occur; and especially so because so many of the fresh-water and land-molluscan types now living on the latter continent are found fossil in its Mesozoic and Cenozoic strata. C. A. WHITE

Washington, D.C., November 4

Velocity of Wind

THE following observations regarding the velocity of the wind in the south-west gale of the 21st and 22nd of November at Edinburgh may be of interest. The observations were made by me about nine o'clock on the morning of the 22nd, when the wind had somewhat moderated :—

	Miles per hour.
Mean velocity	62·3
Velocity during a squall	71·6

These observations are calculated from the velocity of clouds of *smoke* issuing from the chimney of the Caledonian Distillery, and travelling for a distance of 2100 feet, and are thus free from instrumental errors. The chimney is 225 feet high, and its base is about 200 feet above the sea-level.

CHARLES ALEX. STEVENSON

Arctic Research

No one can hold in higher honour and respect than I do the opinions of the greatest of Arctic navigators, Sir Edward Parry, although these opinions were expressed more than half a century ago, since when our knowledge of Arctic shores has very materially increased.

My letter in NATURE vol. xxv. p. 53, where alluding to navigable waters through channels, &c., in the Arctic Sea, specially referred to Arctic America and the lands lying north of it, in which category Greenland can scarcely be included, certainly not that part of its western shores along which a navigable passage is almost invariably to be found.

The following passages from the extract from "Sir Edward Parry's writings" (NATURE, vol. xxv. p. 78) are those which specially bear upon the statements made by me :—

"We experienced a striking example of this kind [ice obstruction] in coasting the eastern shore of Melville Peninsula in 1822 and 1823, the whole of the coast being so loaded with ice as to make the navigation extremely difficult and dangerous."

I do not in the least doubt this, but difficulties of ice-navigation are comparative, and I believe from Eskimo report that the opposite side of Fox's Channel would have been worse. On asking the natives of Repulse Bay why they did not go over to Southampton Island, which forms the eastern shore (having a western aspect) of Sir Thomas Roe's Welcome, the reply was, there were no seals or walruses there, the ice being too much on shore. The same is said of the east side of Fox's Channel.

The sea on the west side of Melville Peninsula is said never to be free from ice[1]; such was its condition during the summer of 1846; and in 1847, when I traced its whole shore, there was a fringe of heavy and rugged hummocks some miles wide all the way.

In the springs of 1847 and 1854 the opposite coast, being the west side of Committee Bay—having an eastern aspect—bore evidence, by the small quantity of rough ice met with, that there had been navigable water at some time during the previous summer.

There can, as a rule, be no better or truer guide to the *side* of a channel, inlet, &c., which is *least* ice-obstructed than the assembling of marine animals, seals, walruses, and whales (provided always that these animals have not been driven away by constant attacks to less favoured resorts) along its shores, on which the Eskimos have their chief camping-grounds, and of

[1] See Rae's "Arctic Expedition," 1846-7, p. 49.

which there are many along the east shore of Melville Peninsula and southward on the same coast-line to lat. 64°, near which the Americans have had their chief whaling and sealing stations for many years.[1]

On August 19 and 20, 1859, Sir Leopold McClintock ran 150 miles down Prince Regent's Inlet, along the side, having an eastern aspect, to Bellot Strait, without seeing a bit of ice except one large iceberg, and returned by the same route in 1860 (August 10 to 16), but on this occasion was stopped near Fury Point by ice, forced in by a strong easterly breeze of four days' duration; when the wind changed to west the obstruction was speedily removed, and there was no farther difficulty. Dundee whalers have not infrequently visited Cresswell Bay in this locality, and killed whales there. So much for shores having an eastern aspect being navigable, notably that of Smith Sound.

The second passage from "Parry's Writings" I wish to comment upon is—

"These facts, when taken together, have long impressed me with the idea that there must exist in the Polar regions *some general motion of the sea towards the west*, causing the ice to set in that direction, when not impelled by contrary winds or local or occasional currents."

When it can be proved that permanent currents exist in the sea, irrespective of wind influence, we must naturally assume that the motion of the sea and of the ice floating on it is in the same direction.

The *Resolute*, one of Sir Edward Belcher's ships, abandoned near the south entrance of Wellington Channel in 1854, must have driven eastward for 300 miles through Barrow Strait and Lancaster Sound, into Baffin's Bay, and was picked up far to the south by the Americans some years afterwards.

Sir Leopold McClintock in 1859 and 1860 found Bellot Strait free from ice, and quite navigable, entering from the east, but impenetrably blocked with thick old ice-floes at its western extremity. In his chart is a note: "Bellot Strait, flood and *permanent* current to eastward."

Sir Edward Parry experienced a somewhat similar permanent easterly current in the Strait of the Fury and Hecla, as the following extract from Capt. Lyon's (who commanded one of Parry's ships) journal (p. 275) will show: "That there was a prevailing set from the westward we had long known, even before entering the strait, and we saw by the driving of the loose ice against an easterly wind that it ran with great force. As an extraordinary instance in point, the *Hecla* broke adrift on the 13th in consequence of a piece of ice parting, and was carried (eastward) against a fresh easterly breeze, about a mile from the fast floe. All sail being set before the wind, we were nearly two hours in recovering this one mile, though to all appearance and by the log going between three and four knots through the water."

Here are examples of two permanent currents running to the east, through straits narrow, it is true, but the only passages known to exist in two lands extending about six degrees, or 360 miles north and south.

The conclusion to be arrived at seems to be, that the sea to the west of these lands is at a higher level than it is to the east of them, and consequently if the general motion of the "sea is towards the west," according to Sir Edward Parry's idea, it must, in the localities named, be moving in opposition to its own currents, or up hill. 4, Addison Gardens, November 26

ARE not the facts of ice-accumulations at "the western sides of seas or inlets," mentioned in your last number (p. 78), to be explained by reference to Baer's law for the flow of rivers? This law, corroborated by many observers in all parts of the world (see for instance NATURE, vol. xv. p. 207), states, as a simple consequence of the earth's rotation, the deviation to the right bank of all rivers of the northern hemisphere running north and south, *i.e.* to the west, if the flow is from the north, and to the east if from the south. Considered from this point of view, it may suffice that the masses of ice are borne by currents from the north, to account for the accumulations on the western borders of these currents, *i.e.* on "the eastern coast of any portion of land." I am well aware that the principle in question was applied to the theory of ocean-currents, long ere C. E.

[1] Along this shore, seal, walrus, and the right whale abounded in 1846, 1847, and 1853, when I was there. In 1854 constant easterly winds kept the ice close to the land for ten days, so that few marine animals were seen during that time.

von Baer extended it to the phenomena of rivers; the above case may be considered as connecting together both classes of phenomena.

Spectrum of the Electric Light

WILL you, or one of your spectroscopical contributors, kindly inform me in what respects (if at all) the spectrum of the electric light differs from that of the sun? At a time apparently not far distant from the almost universal application of the electric light, the question I ask is not unimportant, as it, I believe, affects the tolerance of the human eye for other than solar light. It is already well known that much work done by gas-light is by many found prejudicial to their vision, and this may, I presume, be caused by the inherent qualities of the light. It will be interesting to me therefore to learn in what respects electric light and gas-light differ from solar, as shown by spectrum analysis.

A GLIMPSE THROUGH THE CORRIDORS OF TIME[1]

II.

AT the remote epoch of which we are speaking the solar tides were very small, as they are at present. Yet, small as they are, there was a particular circumstance which may have enormously increased their importance. The point to which I refer can be illustrated very simply. We have here a weight of 14 lbs. freely suspended, and here I have a small wooden mallet which barely weighs half an ounce, yet small as this mallet is, I can make the heavy weight swing by merely giving it blows with the mallet. Let me try. I give the weight blow after blow. I hit it as hard as I can, yet the weight hardly swings. I have not yet been successful. The art of succeeding is merely to time the blows properly; this I am now doing, and you see the weight swings in an arc which is steadily augmenting.

We therefore see that a succession of impulses, in themselves small, can yet produce a great effect when they are properly timed. In the present case the impulses should succeed each other at the same interval as this pendulum requires for one to and fro oscillation. The time therefore depends on the body struck, and not at all on the body which gives the impulses.

Just as this pendulum swings with a definite period so the vibrations of the primæval earth had a certain period appropriate to them. Suppose that the liquid primæval globe were pressed in on two quadrants and drawn out on the two others, and that the pressures were then released. The globe would attempt to regain its original form, but this it could not do at once, any more than the pendulum can at once regain its vertical position; the protruded portions would go in, but they would overshoot the mark, and the globe would thus oscillate to and fro. Now it has been shown that the period of such oscillations in our primitive globe is about an hour and a half, or very close to half the supposed length of the day at that time. The solar tides, however, also have a period half the length of the day. Here then we have a case precisely analogous to the 14 lb. weight I have just experimented on. We have a succession of small impulses given which are timed to harmonise with the natural vibrations. Just as the small-timed impulses raised a large vibration in the weight, so the small solar tides on the earth threw the earth into a large vibration. At first these vibrations were small, but at each succeeding impulse the amplitude was augmented until at length the cohesion of the molten matter could no longer resist: a separation took place: one portion consolidated to form our present earth; the other portion consolidated to form the moon.

There is no doubt whatever that the moon was once quite close to the earth; but we have to speculate as to what brought the moon into that position. I have given you what I believe to be the most reasonable explanation, and I commend it to your attention. There are difficulties about it, no doubt: let me glance at one of them.

I can easily imagine an objector to say, "If the moon were merely a fragment torn off, how can we conceive that it should have that beautiful globular form which we now see? Ought not the moon to have rugged corners and an irregular shape? and ought not the earth to show a frightful scar at the spot where so large a portion of its mass was rent off."

You must remember that in those early times the earth was not the rigid solid mass on which we now stand. The earth was then so hot as to be partially soft, if not actually molten. If then a fragment were detached from the earth, that fragment would be a soft yielding mass. Not for long would that fragment retain an irregular form; the mutual attraction of the particles would draw the mass together. By the same gentle ministrations the wound on the earth would soon be healed. In the lapse of time the earth would become as whole as ever, and at last it would not retain even a scar to testify to the mighty catastrophe.

I am quite sure that in so large and so cultivated an audience as that which I am now addressing, there are many persons who take a deep interest in the great science of geology. I believe however that the geologist who had studied all the text-books in existence might still be unacquainted with the very modern researches which I am attempting to set forth. Yet it seems to me that the geologists must quickly take heed of these researches. They have the most startling and important bearing on the prevailing creeds in geology. One of the principal creeds they absolutely demolish.

I suppose the most-read book that has ever been written on geology is Sir Charles Lyell's "Principles." The feature which characterises Lyell's work is expressed in the title of the book, "Modern Changes of the Earth and its Inhabitants considered as Illustrative of Geology." Lyell shows how the changes now going on in the earth have in course of time produced great effects. He points out triumphantly that there is no need of supposing mighty deluges and frightful earthquakes to account for the main facts of geology.

Lyell attempts to show that the present action of winds and storms, of rains and rivers, of ice and snow, of waves and tides, will account for the formation of strata, and that the gentle oscillations of the earth's crust will explain the varying distribution of land and water. In this we can to a great extent follow him. I am quite satisfied with the oscillations in the land. If the land rises an inch or two every century in one place and falls to the same extent elsewhere, all that is required has been explained. Nor do I feel at present disposed to question his views as to rivers or to glaciers, to rains or to winds. There is however one great natural agent of which Lyell does not take adequate account. He does not attach enough importance to the tides. No doubt he admits that the tides do some geological work. He even thinks they can do a great deal of work. The sea batters the cliffs on the coasts, and wears them into sand and pebbles. The glaciers grind down the mountains, the rains and frosts wear the land into mud, and rivers carry that mud into the sea. In the calm depths of ocean this mud subsides to the bottom; it becomes consolidated into rocks; in the course of time these rocks again become raised, to form the dry land with which we are acquainted.

The tides, says Lyell, help in this work. Tidal currents aid in carrying the mud out to sea; they aid to a considerable extent in the actual work of degradation, and

[1] Lecture delivered at the Midland Institute, Birmingham, on October 24, 1881, by Prof. Robert S. Ball, LL.D., F.R.S., Andrews Professor of Astronomy in the University of Dublin, and Royal Astronomer of Ireland. Contributed by the Author. Continued from p. 82.

thus contribute their quota to the manufacture of stratified rocks. Such is the modest *rôle* which Lyell has assigned to the tides, and no doubt the majority of geologists have acquiesced in this doctrine. Nor can there be any doubt that this is a just view of tidal action at present. That it is a just view of tidal action in past times is what I now deny. Lyell did not know—Lyell could not have known—that our tides are but the feeble surviving ripples of mighty tides with which our oceans once pulsated. Introduce these mighty tides among our geological agents, and see how waves and storms, rivers and glaciers, will hide their diminished heads.

I must attempt to illustrate this view of tidal importance in ancient geological times. Let me try by the aid of the tides to explain the great difficulty which every one must have felt in regard to Lyell's theory. I allude to the stupendous thickness of the Palæozoic rocks.

Look back through the Corridors of Time in the manner in which they are presented to us in the successive epochs of geology. We pass rapidly over the brief career of prehistoric man; then through the long ages of Tertiary rocks, when the great mammals were developed; back again to the much earlier period when colossal reptiles and birds were the chief inhabitants of the earth; back again to those still earlier ages when the luxuriant forests flourished that have given birth to the coal-fields; back once more to the age of fishes; back finally to those earliest periods when the lowest forms of life began to dawn in the Palæozoic era.

As we date remote ages astronomically by the distance of the moon, so we date remote ages geologically by the prevailing organic life. It is a great desideratum to harmonise these two chronological systems, and to find out, if possible, what lunar distance corresponds to each geological epoch. In the whole field of natural science there is no more noble problem. Take, for example, that earliest and most interesting epoch when life perhaps commenced on the earth, and when stratified rocks were deposited five or ten miles thick, which seem to have contained no living forms higher than the humble Eozoon, if even that were an organised being. Let us ask what the distance of the moon was at the time when those stupendous beds of sediment were deposited in the primæval ocean. We have in this comparison every element of uncertainty except one. The exception is, however, all important. We know that the moon must have been nearer to the earth than it is at present. There are many very weighty reasons for supposing that the moon must have been very much nearer than it is now. It is not at all unlikely that the moon may then have been situated at only a small fraction of its present distance. My argument is only modified, but not destroyed, whatever fraction we may take. We must take some estimate for the purpose of illustration. I have had considerable doubts what estimate to adopt. I am desirous of making my argument strong enough, but I do not want to make it seem exaggerated. At present the moon is 240,000 miles away; but there was a time when the moon was only one-sixth part of this, or say 40,000 miles away. That time must have corresponded to some geological epoch. It may have been earlier than the time when the Eozoon lived. It is more likely to have been later. I want to point out that when the moon was only 40,000 miles away, we had in it a geological engine of transcendent power.

On the primitive oceans the moon raised tides as it does at present; but the 40,000-mile moon was a far more efficient tide-producer than our 240,000-mile moon. The nearer the moon the greater the tide. To express the relation accurately we say that the efficiency of the moon in producing tides varies inversely as the cube of its distance. Here then we have the means of calculating the tidal efficiency for any moon distance. The 40,000-mile moon being at a distance of only one sixth of our present moon's distance, its tidal efficiency would be increased $6 \times 6 \times 6$ fold. In other words, when our moon was only 40,000 miles away it was 216 times as good a tide-producer as it is at present.

The heights to which the tides rise and fall is so profoundly modified by the coasts and by the depth of the sea, that at present we find at different localities tides of only a few inches and tides of 60 or 70 feet. In ancient times there were no doubt also great varieties in the tidal heights, owing to local circumstances. To continue our calculation we must take some present tide. Let us discard the extremes just indicated and take a moderate tide of 3-feet rise and 3-feet fall as a type of our present tides. On this supposition what is to be a typical example of a tide raised by the 40,000 mile moon? If the present tides be 3 feet, and if the early tides be 216 times their present amount, then it is plain that the ancient tides must have been 648 feet.

There can be no doubt that in ancient times tides of this amount and even tides very much larger must have occurred. I ask the geologists to take account of these facts, and to consider the effect—a tidal rise and fall of 648 feet twice every day. Dwell for one moment on the sublime spectacle of a tide of 648 feet high, and see what an agent it would be for the performance of geological work! We are now standing, I suppose, some 500 feet above the level of the sea. The sea is a good many miles from Birmingham, yet if the rise and fall at the coasts were 648 feet, Birmingham might be as great a seaport as Liverpool. Three-quarters tide would bring the sea into the streets of Birmingham. At high tide there would be about 150 feet of blue water over our heads. Every house would be covered, and the tops of a few chimneys would alone indicate the site of the town.

In a few hours more the whole of this vast flood would have retreated. Not only would it leave England high and dry, but probably the Straits of Dover would be drained, and perhaps even Ireland would in a literal sense become a member of the United Kingdom. A few hours pass, and the whole of England is again inundated, but only again to be abandoned.

These mighty tides are the gift which astronomers have now made to the working machinery of the geologist. They constitute an engine of terrific power to aid in the great work of geology. What would the puny efforts of water in other ways accomplish when compared with these majestic tides and the great currents they produce?

In the great primæval tides will probably be found the explanation of what has long been a reproach to geology. The early palæozoic rocks form a stupendous mass of ocean-made beds which, according to Prof. Williamson, are twenty miles thick up to the top of the silurian beds. It has long been a difficulty to conceive how such a gigantic quantity of material could have been ground up and deposited at the bottom of the sea. The geologists said, "The rivers and other agents of the present day will do it if you give them time enough." But unfortunately the mathematicians and the natural philosophers would not give them time enough, and they ordered the geologists to "hurry up their phenomena." The mathematicians had other reasons for believing that the earth could not have been so old as the geologists demanded. Now, however, the mathematicians have discovered the new and stupendous tidal grinding-engine. With this powerful aid the geologists can get through their work in a reasonable period of time, and the geologists and the mathematicians may be reconciled.

I have here a large globe to represent the earth, and a small globe suspended by a string to represent the moon. At the commencement of the history the two globes were quite close; they were revolving rapidly, and the moon was constantly over the same locality on the primæval earth. I do not know where that locality was; it was probably the part of the earth from which the moon had

been detached. No doubt it was somewhere near the equator, but the distinction of land and water had not then arisen. Around the primæval earth the moon revolved in three hours; the earth also revolved in three hours, so that the moon constantly remained over the red region. This I can illustrate by holding the small globe which represents the moon in one hand, and making the large globe which represents the earth revolve by the other.

This state of things formed what is known as unstable dynamical equilibrium. It could not last. Either the moon must fall back again on the earth, and be reabsorbed into its mass, or the moon must commence to move away from the earth. Which of these two courses was the moon to take? The case is analogous to that of a needle balanced on its point. The needle must fall some way, but what is to decide whether it shall fall to the right or to the left? I do not know what decided the moon, but what the decision was is perfectly plain. The fact that the moon exists shows that it did not return to the earth, but that the moon adopted the other course, and commenced its outward journey.

As the moon recedes, the period which it requires for a journey round the earth increases also. Initially that period was but three hours, and it has increased up until our present month of 656 hours.

The rotation of the earth has been modified by the retreat of the moon. Directly the moon began to retreat the earth was no longer under an obligation to keep the same face thereto. When the moon was at a certain distance the earth made two rotations for every revolution that the moon made. Thus as I carry the small globe round the large globe the latter makes two revolutions for one revolution of the small globe. Still the moon gets further and further away, until the earth performs three, four, or more rotations for each of the moon's revolutions. Do not infer that the rate of the earth's rotation is increasing; the contrary is the fact. The earth's rotation is getting slower, and so is that of the moon; but the retardation of the moon is much greater than that of the earth. Even though the rotation of the earth is much more than the primitive three hours, yet that of the moon has increased to several times the rotation of the earth.

The moon recedes still further and further, and at length a noticeable epoch is reached, to which I must call attention. At that epoch the moon is so far out that its revolution takes twenty-nine times as long as the rotation of the earth. The month was then twenty-nine times the day. The duration of the day was less than the present twenty-four hours, but I do not believe it was very much less. The time we are speaking of is not very remote, perhaps only a very few million years ago. The month was then in the zenith of its glory. The month was never twenty-nine times as long as the day before. It has never been twenty-nine times as long as the day since. It will never be twenty-nine times as long as the day again.

Resuming our history, we find the moon still continuing to revolve in an ever-widening circle the length of the month and of the day both increasing. The ratio of the day to the month was still undergoing a change. When the moon was a little further off the earth only revolved twenty-eight times instead of twenty-nine times in one revolution of the moon. Still the velocity of the earth abates until it only makes twenty-seven revolutions in one revolution of the moon. This is an epoch of especial interest, for it is the present time. In the present order of things the moon revolves round the earth once while the earth rotates twenty-seven times. This has remained sensibly true for thousands of years, and no doubt will remain sensibly true for thousands of years to come, but it will not remain true indefinitely. Wondrous as are the changes which have occurred in times past, not less wondrous are the changes which are to occur in time to come. The tides have guided our gropings into the past; they will continue to guide our researches to make a forecast of the future.

Further and further will the moon retreat, and more and more slowly will the earth revolve. But we shall not pause at intervening stages; we shall try to sketch the ultimate type to which our system tends. In the dim future, many millions of years distant, the final stage will be approached. As this stage draws nigh, the rotation of the earth will again approach to equality with the revolution of the moon. From the present month of twenty-seven days we shall pass to a month of twenty-six days, of twenty-five days, and so on, until eventually we shall reach a month of two days, and lastly a month of one day. When this state has been attained the earth will constantly turn the same region towards the moon. I do not know what is the locality on the earth which is destined for this distinction.

Here you see that the first state and the last state of the earth-moon history are in one sense identical. In each case the same face of the earth is constantly directed towards the moon. In another way, how different are the first stage and the last. At the beginning the day and the month were both equal, and they were each three hours. At the end the day and the month will be again equal, but they will each be 1400 hours. The moon will then go round the earth in 1400 hours, while the earth will rotate on its axis in the same time. In other words, the day is destined in the very remote future to become as long as fifty-seven of our days. This epoch will assuredly come if the universe lasts long enough. When it has come it will endure for countless ages. It would endure for ever if the earth and the moon could be isolated from all external interference.

We heard a great deal a few years ago about the necessity of shortening the hours of labour. I wish to point out that the social reformers who are striving to shorten the hours of labour are pulling one way, while the moon is pulling the other. The moon is increasing the length of the day. The change will be very gradual, but none the less is it inevitable. Where will the nine-hours' movement be when the day has increased to 1400 hours? This will be a very serious matter, and there is only one way by which it can be avoided. The question is one rather for engineers than for astronomers; but I cannot help throwing out a suggestion. My advice is: Anchor the moon, and keep it from going out. If you can do this, and if you can also provide a brake by which the speed of the moon can be controlled, then you will be able for ever to revel in the enjoyment of a twenty-four-hour day.

Should this engineering feat never be accomplished, then we have only the 1400-hour day to look forward to. Nor is there anything untoward in the prospect, when we take natural selection as our comforter. By natural selection man has become exactly harmonised with his present environment. No doubt natural selection moves at a dignified pace, but so in all truth does tidal evolution. Natural selection and tidal evolution have advanced *pari passu* through all the past millions of geological time. They will advance *pari passu* through all the ages yet to come. As the day lengthens, so will man's nature gradually change too, without any hardship or inconvenience. All that is necessary is plenty of time. Should we think it a hardship that our children should have a day of twenty-four hours and one second instead of twenty-four hours? That the day enjoyed by our grandchildren should be a second longer than the day of our children? That the day of our great-grandchildren should be a second longer still, and so on continually? This would be no inconvenience whatever. No one except the astronomers would be able to detect the change, and daily life would be unaltered. Yet, carry on this process for only 150 million years, and we shall find that the whole change of the day from

twenty-four hours to 1400 hours has been accomplished. The actual rate of change is indeed much less than this, and is at present so small that astronomers can hardly even detect it.

Our remote posterity will have a night 700 hours long, and when the sun rises in the morning 700 hours more will elapse before he can set. This they will find a most suitable and agreeable arrangement. They will look back on our short periods of rest and short periods of work with mingled curiosity and pity. Perhaps they will even have exhibitions of eccentric individuals able to sleep for eight hours, work for eight hours, and play for eight hours. They will look on such curiosities in the same way as we look on the man who undertakes to walk a thousand miles in a thousand hours.

I am beyond all things anxious to give you the impression that I am not indulging in any mere romance. No doubt the various figures I have mentioned are but estimates. They may be found to require correction—perhaps large correction; but the general outline of the theory must be true. Should any traces of doubt still linger in the mind of some prejudiced person, let me finally dissipate them. Perhaps some caviller may say, Where are the proofs of all this action of the tides? How do you know that the tides are sufficiently powerful to produce such changes? I believe I have shown this abundantly, but some people require a great deal of conviction. I have therefore kept my best argument for the end.

For an overwhelming proof of tidal efficiency I shall summon the heavens themselves to witness, and I shall point to the stupendous task which tides have already accomplished. As the moon has made and is making tides on the earth, so the earth once raised tides on the moon. These tides have ceased for ages; their work is done; but they have raised a monument in the moon to testify to the tidal sufferings which the moon has undergone. To that monument I now confidently appeal. The moon being much smaller than the earth, the tides on the moon produced by the earth must have been many times as great as the tides on our earth produced by the moon. It matters not that the moon now contains no liquid ocean. Nor does it matter whether the moon ever had a liquid ocean. In very ancient days the moon was not the hard, rigid mass which it now appears. Time was when the volcanoes raged on the moon with a fury which nothing on our earth at present can parallel. The moon was then in a soft or a more or less fluid condition, and in this viscous mass the earth produced great tides.

Great tides in truth they were, for the earth is eighty times as heavy as the moon. On the other hand, the moon is only one-fourth the diameter of the earth; so that the actual height of the tides on the moon would be still many times as great as the tides on the earth. When the moon was nearer to us, as it was in early ages, those tides were still greater. Think for one moment of what a lunar tidal wave of such magnitude would be capable. This wave is perhaps of molten lava; it would tear over the surface with terrific power, and anything that friction could accomplish that great current would do. That tidal current has done its work; even if the moon were fluid at the present day it could no longer be distracted by tides. Remember, it is not the mere presence of the tide which produces friction. It is the action of the tide in rising and in falling which accomplishes the work. If, therefore, the moon moved so that it was always high tide at the same place, the tides could produce no further effect. The spot where the tide is high on the moon is the spot which is towards the earth. It hence follows that the action of the tides will cease when the moon constantly directs the same face to the earth. The moon has thus at length gained a haven of rest from a tidal point of view. No doubt the moon has a high tide and it has a low tide, but those tides no longer ebb and flow: the moon has succumbed to the incessant action of friction, and has assumed the only attitude which can relieve it from incessant disturbance.

For many centuries it had been an enigma to astronomers why the moon should always turn the same face to the earth. It could be shown that there were many million chances to one in favour of this being due to some physical cause. The ordinary theory of gravitation failed to explain the cause. Every one had noticed this phenomenon. Yet the explanation was never given till lately. It was Helmholtz who showed that this was a consequence of ancient tides, and this simple and most satisfactory explanation has been universally accepted. The constant face of the moon is a living testimony to the power of the tides. What tides have accomplished on the moon is an earnest of what tides will accomplish on the earth.

In the great conflict of the tides the earth has already conquered the moon, and forced the moon to render perpetual homage as a token of submission. Remember, however, that the earth is large, and the moon is small. Yet small though the moon is, it gallantly struggles on. "You have forced me," cries the moon to the earth, "to abandon the rotation with which I was originally endowed; you have compelled me to rotate in the manner you have dictated. I will have my revenge. It is true I am weak, but I am unrelenting; day by day I am exhausting you by the tides with which I make you throb. The time will assuredly come, though it may not be for millions of years, when you shall be forced to make a compromise. When that compromise is made the turmoils of the tides will cease; our mutual movements will be adjusted. With equal dignity we shall each rotate around the other; with equal dignity we shall each constantly bend the same face to the other."

There is another point to be considered. We must not forget that there is a sun in the heavens as well as a moon. The sun also produces tides in the earth. Those tides were much smaller than the lunar tides, so that we could afford to neglect them. But we have seen that the lunar tides will gradually decrease to nothing. It behoves us then to consider what the solar tides can effect which shall be worthy of our attention. In a lecture which I gave here some years ago, I made allusion to the discovery of the satellites of Mars. I mentioned that one of the satellites of Mars presented a phenomenon unparalleled in the solar system. The satellite revolved around Mars in a period of seven hours, while Mars himself rotated on his axis in a period of twenty-four hours. We here actually find the moon of Mars rotating around Mars in much less than one of Mars' own days. This was a most curious and unexpected circumstance, but the observations of the discoverer, Asaph Hall, placed the great fact beyond any doubt. The mystery has now been explained. It is due to the action of the solar tides on Mars. Nay more, we can actually foresee that at some incredibly remote future time our earth and moon are destined to present the same movements which have seemed so anomalous in Mars.

Left to themselves, the earth and the moon would have remained for ever in the condition of compromise. The moon would have revolved round the earth in 1400 hours. The earth would have rotated on its axis in 1400 hours also. But now the solar tides intervene. They have little effect upon the moon; it revolves as before, but the solar tides begin to retard the earth still further. Instead of a period of 1400 hours, the earth will have a still longer day, so that finally the moon revolves more rapidly around the earth than the earth rotates on its axis.

It seems to me that the episode I have mentioned is one of the most interesting in the whole of modern astronomy. We have first a most delicate telescopic discovery of the tiny satellite of Mars and of its anomalous movements. We then have a beautiful explanation of how

this anomalous motion has arisen from the action of solar tides. Finally we have in this miniature system of Mars a foreshadowing of the ultimate destiny of our earth and our moon.

Do I say the ultimate destiny? Nothing is ultimate in nature. The moon and the earth would have come to an amicable and a final agreement had they been let alone. But now the sun has intervened and disturbed the earth's rotation. The truce once broken, the moon again produces tides on the earth, the earth reacts on the moon, and a whole chain of complicated movements are the consequence. I shall not now attempt to trace the further progress of events.

I have dealt with very large figures in this lecture, and perhaps I have taxed your imagination by my demands that you should conceive of periods of tens of millions of years. Yet after all let us look at the results in their true proportion, compared with the universe in which our lot has been cast.

Truly we have been engaged with a very trifling matter. Is not our earth one of the most insignificant bodies in the universe? And our moon is much smaller still. Nor is it even the life-history of our earth that we have been considering, it is merely a brief episode in that history. What are the periods of time we have been discussing when compared with those infinitely longer periods during which the solar system has been evolved? Even the solar system is but one out of one hundred million such systems, each of which has its own life-history. Viewed in their true proportions, the phenomena I have described are but of infinitesimal importance, and the time they have occupied is merely ephemeral.

No doubt we have only dwelt upon the tides on the earth and the tides in the moon, which have been of such infinite importance. But do not suppose that tides are confined to the earth and to the moon. So far as we know, every body in the universe is capable of producing, and actually does produce, tides in every other body. Every planet throbs in response to the tides produced in it by every other planet. Every star has a distinct tidal wave produced in it by every other star. You may say that such tides are infinitesimal, but you must remember that infinitesimal causes, sufficiently often repeated, can achieve the mightiest effects.

We know that tides have wrought our solar system into its present form; and are we to say that the wondrous powers of the tide have no grander scope for their exercise? I prefer to believe that tides operate far and wide through the universe, and that in the recognition of the supreme importance of tidal evolution we mark a great epoch in the history of physical astronomy.

POPULAR NATURAL HISTORY[1]

THE present volume of this finely illustrated work finishes the account of the Vertebrates with the history of the Fishes, and gets over as well an immense mass of the Invertebrates. The story of the Fishes is contributed by Prof. H. G. Seeley, who, in the limited compass of 150 pages, of which about one-sixth is occupied with figures, has given a very fair and comprehensive notice of this class. The Fishes are the only primary division of the Vertebrata which live in water, and have no representatives passing their lives upon land or in the air. This condition of existence is probably the cause of the close correspondence in bodily form in the majority of fishes, which progress through the water chiefly by movements of the tail, and use the fins as organs with which to steer a path. "Clear as is the idea which rises in the mind at the mention of a fish, the multitude of forms which fishes exhibit are greater, perhaps, than those to be found in any of the other great groups of Vertebrate animals described in the previous four volumes of this series. The slender form of the lamprey or eel contrasts with the expanded body of the turbot or the plaice; the short deep form of the sun-fish is unlike the broad, flattened, and long-tailed skate; the sea-horses, when attached to sea-weeds by their prehensile tails, at first sight present none of the familiar characteristics of fishes. The flying-fish, which have the fins so expanded as to serve some of the purposes of wings, present a remarkable contrast to the spheroidal spiny body of the globe-fish, while the hammer-headed shark exhibits a form of body in some respects more singular still. When we turn to details of proportion and structure, and contrast the shapes of the head or of the tail, the variety among fishes is altogether exuberant."

As an illustration of the woodcuts to be found plentifully in this volume, we select a sea-horse some time since described by Dr. Günther, the strange *bizarre* form of which will at once attract attention. The illustration is a very fair copy of the beautifully-drawn figure of Mr. Ford in the *Proceedings* of the Zoological Society of London for 1865, and represents, of the natural size, a specimen of *Phyllopteryx eques* from South Australia. "There is no doubt," writes Dr. Günther, "that these fish attach themselves with the prehensile end of their tails to stems of sea-weed and other objects; and when they are in the vicinity of sea-weed of a similar colour to themselves, their resemblance to it must be so great that they would easily escape being observed by their enemies." We fancy that Prof. Seeley is wrong in stating that, "as the name implies, this fish has very much the aspect of a moving plant." The idea in Swainson's mind was doubtless nearer to the actual meaning of the words he formed the generic title from—that of leaf-winged—and we may venture to call Dr. Günther's species the Leaf-finned Sea-horse.

The section on Fossil Fishes is very short, but a great deal of information is contained therein. "A large proportion of fossil fishes belong to the division Palæichthyes. This group comprises most of the fishes which have been met with in the primary rocks and many of those found in the Secondary strata; but in Tertiary deposits the Teleostean division is quite as well represented in the geological formations as in existing seas. There is no evidence of any gradual succession of fishes in the order of increased complicity of structure, as the deposits in which they occur approach nearer to the present day, and there is no reason to suppose that the oldest fishes known were the first that appeared upon the earth. The earliest fishes discovered were met with in the Lower Ludlow rocks, which form the upper part of the Silurian strata. The most ancient genus is Scaphaspis, a small buckler-headed fish, which had the body covered with scales. Many allied genera are found in the overlying Old Red Sandstone, in which fishes appear in extraordinary variety. Among the allies of Scaphaspis are Pteraspis, Cephalaspis, &c., some of which range down to the Silurian rocks. Near to these fishes must be placed Coccosteus, Pterichthys, and the immense American fossil of Devonian age named Dinichthys. These fishes are thought to be related to Ganoids and Sharks, but in external form they more closely approximate to Loricaria, though the tail is heterocercal. They form a distinct group named Placodermi."

While four volumes and a goodly portion of a fifth are devoted to the Vertebrata, there are not wanting signs that the immense divisions of the animal kingdom here grouped as Invertebrata are to be treated of after the usual stereotyped fashion, and that at most one further volume will bring this series to a close. The Invertebrata, we are told, are divided into great types, or groups, which are (1) the Mollusca; (2) the Arthropoda; (3) the Vermes; (4) the Echinodermata; (5) the Zoophyta; and (6) Protozoa. "These great divisions are not exactly

[1] "Cassell's Natural History." Edited by P. Martin Duncan, M.B., F.R.S. Vol. v., illustrated. (London: Cassell, Petter, Galpin, and Co., 1881.

defined in nature, and they are subdivided into secondary groups, and are also united in some instances by forms of life which cannot well be placed in any particular one." We presume these "latter forms of life" are those called "intermediate groups," which are "(1) the Tunicata, which have a more or less leathery or cartilaginous covering sac." "They may be placed in the neighbourhood of the Vermes and Mollusca in their classification." "(2) The Molluscoida, which have the body with shells placed differently to those of the Mollusca, or have a tubular or shell-like covering." "The Bryozoa and Brachiopoda are included in this group, and in their structures, embryonic and adult, they show resemblances to those of Vermes, Mollusca, and Tunicata."

The chapters on Mollusca and Tunicata are by Dr. Henry Woodward; the Bryozoa and Brachiopoda by Agnes Crane; the introduction to Insecta and the account of the order of the Hymenoptera is from the pen of Mr. Dallas, and the chapter on the order of Coleoptera is by Mr. Bates. In passing we may note that the reader will find no hint that the Arthropods are jointed-limbed animals containing the Crustacea and Arachnids, unless incidentally when Mr. Dallas is describing the true Insect type.

It is scarcely necessary to state that within the limits at his disposal Dr. H. Woodward has given a very interesting account of the Molluscan forms. We are glad to note too that he has devoted a good portion of his space to an account of the Cuttle-fishes, which is more exciting and interesting reading than the necessarily brief accounts of such families as those of Cancellariadæ and Pyramidellidæ. The chapter on that "intermediate type," the Tunicata, is poor indeed, and not what we should have expected from its author. Surely we have

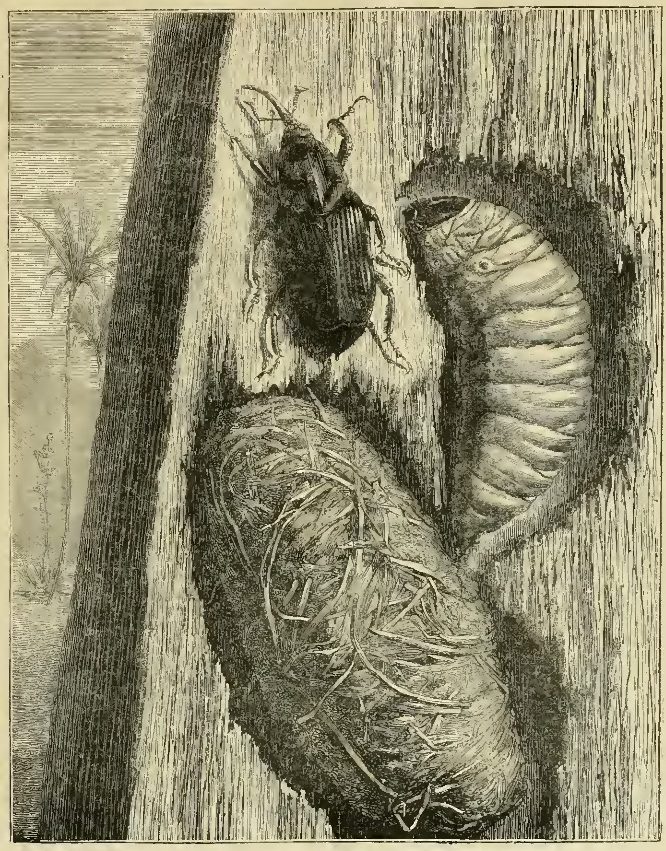
The Leaf-finned Sea-horse.

learned something more of this group since the writings of Forbes and Savigny.

The chapters on the Brachiopoda and Bryozoa by Agnes Crane appear to be extremely carefully written. The illustrations—many of them—are refreshingly new, and taken from the best of sources. We altogether disagree with the authoress as to adopting the name of Bryozoa for the group she calls Sea-mosses, but she states the case for and against the use of the term Polyzoa most fairly; and nowhere have we met a more neatly compiled account, brought down, too, to the very latest date of this group—even the facts brought to light by the expedition of the *Challenger* are alluded to therein.

The introduction to the group of Insects is remarkably well done. The classification is primarily based on the presence or absence of a perfect metamorphosis, and the secondary divisions are based on the structure of the mouth. As for certain small groups of insects which undergo no metamorphosis at all, "They may be residues of groups formerly more numerous and abundant, in which case they ought probably to be kept distinct from the other existing orders of Insects," or as we prefer to think, "they may be degraded representatives of the orders to which they appear to be most nearly related." The account of the first order on the list, that of the Beetles, is written by H. W. Bates, and few possess more knowledge of the many forms that compose this group. It need not be said that he does not attempt to treat of the 80,000 and upwards of known forms in the fifty pages at his service, but from what he tells us of the habits of those he does describe, we feel our interest in the subject increasing, until, when we come to the account of the Ladybirds, "upwards of 1500 species of which are known," we feel sorry that we have come to the very last line long ere the author had evidently come to the last of his subject.

We give, through the courtesy of the publishers, another illustration taken from the chapter on Weevils. It is of a weevil known as *Rhyncophorus palmarum*. Its fat grubs live on the stems of palm-trees, and are often very destructive. Several of the species are very injurious to the sugar-cane. One found in sugar-plantations in Guiana contain in their intestines lumps of a sweet waxy substance—the altered saccharine food on which they live—and for this they are boiled and eaten by the natives. The fine fat larva and the pupal condition, as well as the full-grown weevil, are to be seen in the engraving.



The Palm Weevil.

The account of the immense and important order of the Hymenoptera is written by Mr. Dallas; but only the history of the Aculeata is here given, and the other sections are reserved until the succeeding volume.

AMI BOUÉ

THE decade which closes this year will remain a memorable one in the annals of geology for the great names which appear in its obituary. Not a few of the early leaders, to whom it was possible to master fully every department of the infant science and to strike out into new untrodden paths in almost any direction, have lived on to witness the vast development of the studies which they did so much to foster. In this country we have lost only lately Murchison, Sedgwick, Lyell, Phillips, Scrope, whom we early learnt to reverence as demi-gods of the heroic age. And now to these names another falls to be added which, though not that of a Briton, has long been a household word among the geologists of this country. The veteran Ami Boué has just passed away. Ripe in years and universally honoured, he has remained perched on his beloved mountain slopes like a boulder stranded above the reach of the all-devouring sea. But the tide of mortality has at last swept him away, and has thus broken one of the most interesting ties that bound us to the early days of geology. Having for many years enjoyed

the privilege of his friendship and having heard from his own lips many of the incidents of his life, I am able to give here a few personal reminiscences which may be of general interest at the present time, without at present attempting to offer any summary or review of the scientific work of his life. It is much to be desired that his own notices of his life should be published. His early wandering years were especially eventful, and their history is intimately bound up with that of the science which he cultivated with so much ardour.

Ami Boué was born, so far as I can make out, on March 16, 1794, so that he had reached the eighty-eighth year of his age. He was descended of an old French family, and could trace his pedigree back for some four centuries. In the time of Louis XIV., when so large a part of the Protestant population fled on the Revocation of the Edict of Nantes, his ancestor escaped from Bordeaux in a barrel. The family went first to Amsterdam, and finally settled at Hamburg. His mother's family belonged to an Alsatian stock, by name Roth-Hut, which, when they came to Geneva, was changed into Chapeaurouge. She was the daughter of a rich merchant who had established himself at Hamburg, but she was sent at an early age to her relatives in Geneva. Hence French became her early, and to the end of life her natural, language, for though she returned to Hamburg and married there, she never acquired fluency in German, and French was the language in which she always talked to her children. Thus, though born in Hamburgh, Boué spoke and wrote French, and not German, as the language of his boyhood. Both his father and mother appear to have died when he was still very young. He was accordingly sent to the care of his uncles in Geneva to be educated. It was intended that he should enter the mercantile life, in which most of his relatives were engaged. But at that time the French were menacing Hamburg, and the state of Europe was so unquiet that his guardians, deeming him safer in Geneva, kept him there studying jurisprudence. His tastes were already, however, strongly turned towards natural science, and he threw himself heartily into the pursuit of mineralogy and botany. He was accordingly allowed to prosecute these studies, in which he made considerable progress. The political horizon continuing still ominously dark, Boué's future was somewhat uncertain. There was family property enough in Hamburg to secure a small competence for himself and his brothers; but it consisted of property and stock which might be destroyed by the French, as had happened already to one of his uncles. So his guardians determined that he ought to have some profession to fall back upon in case of the destruction of the Hamburg property. He chose medicine as the career that promised most facilities for prosecuting natural history studies. Britain offering at that time the only safe retreat for him, he was sent to the medical school of Edinburgh University. As he used to say himself, "I really went to Scotland to escape from Napoleon." Coming with good introductions from Prevost of Geneva and others to Dugald Stewart and other eminent men, he found a welcome in the most cultivated society of Edinburgh. For three months he employed himself principally in acquiring English, which he eventually mastered sufficiently to be able to read it fluently, and with less success to speak and write it. To the end of his long life he was glad of every opportunity of using his knowledge of English. His letters to me were always in English, closely written, without spectacles, in an almost microscopic handwriting, and not seldom sealed with a thistle and "Dinna forget," which he cherished as one of the souvenirs of his student days in Scotland. He studied chemistry under Hope, and took voluminous notes in French, which he had carefully preserved. He knew more botany, he used to say, than his professor, and profited nothing by that class. But the natural history class under Jameson greatly stimulated his mineralogical and geological zeal. In the fortnight between the winter and summer sessions he would always rush off for an excursion into some part of the country with hammer, bag, or vasculum. The long autumn vacation, too, was put to a similar use. In this way he made himself personally familiar with much of the Scottish Highlands, including Mull and Arran. He extended his rambles into the basaltic tracts of the north of Ireland, and visited also the Lake District and part of Derbyshire. Besides receiving the friendly assistance of his teacher, Jameson, he was intimate with Playfair, and accompanied MacCulloch in his yacht round Arran.

Meanwhile events of worldwide importance and of the utmost interest to Boué had been rapidly passing on the Continent. The final disaster at Waterloo, by shattering Napoleon's power, had freed Boué's Hamburg property from all risk of attack, and left him at liberty regarding his future career. He resolved to complete his medical education, and accordingly took his degree at Edinburgh in 1816. During the course of his medical work he had made many researches and experiments with the view of offering as his graduation thesis a treatise, *De Urina*. But finding he could not afford to publish so voluminous a mass of materials as he had collected, he chose another subject to which he had likewise given much attention—the causes of the present geographical distribution of plants. He was at that time much impressed by the writings of Humboldt on kindred topics, and in the course of his rambles over Scotland he had been in the habit of noting carefully the relations between the flora of each district and its geological structure. Accordingly he duly presented to the Senatus a Latin thesis, "De Methodo Floram regionis cujusdam conducendi, exemplis e florâ Scoticâ &c., ductis, illustrata." It was characteristically and gratefully dedicated to his maternal uncles and guardians.

Having graduated as a doctor of medicine at Edinburgh, he left Scotland immediately thereafter, and went to Paris to prosecute his studies in physics and chemistry. While thus engaged he brought together the large collection of notes he had made in Scottish geology, and elaborated them into his well-known "Essai Géologique sur l'Écosse" a work which will always rank as one of the early classics of the science. Unfortunately for the book he left Paris on his travels before it had passed through the press. He placed the revision of the proofs in the hands of a friend, and hence many errors crept both into the text and the plates.

Being now free to move about as he chose, he devoted himself with all the ardour of his enthusiastic nature to the prosecution of geology. He personally visited most of the more interesting tracts of France and Central Europe, but finally devoted himself to the eastern regions, as being those about which least was known. At the age of thirty-two he married a lady six years younger than himself, who accompanied him in many of his journeys, and who now survives him. The best evidence of his constant industry is furnished by the list of papers and memoirs, some 200 in number, which during his long life he published in the scientific journals of Europe. Some of his best work was done in Turkey, of which country indeed he was the first great geological explorer. The volumes in which he embodied the results of his researches there show at once his skill as an observer and the quiet indomitable courage with which he must have faced every kind of privation and even danger. On one occasion, as he told me, he was poisoned by his servant—a nobleman, who leaving him for dead, made off with the carriage and everything belonging to the poor traveller except his watch, which, being only of silver, was not considered worth stealing.

After some years spent in field-work he published at Paris (1835) his excellent "Guide du Géologue-Voyageur,"

in which he gives the sum of his own practical experience, with a digest of what had been done by others. Though much of these two little pocket volumes has been superseded by the progress of science, they remain as an admirable summary of the geology of their time, while many of their sound practical directions may be usefully read and remembered in all time coming. The closing sentences of the preface may be quoted here for their personal reference. "Thrown from my earliest days on the highways of the world, as most of my kin have been, having spent my life among seven capitals of Europe, and having near relatives in a dozen cities of the north-west and centre of this continent, my travelling disposition may be easily understood, and my irresistible tendency to a vagabond life. I was left an orphan at eleven years, and became entirely master of my own movements at twenty. This want of a fixed residence, this facility of moving about and making myself at home everywhere, adopting the customs and language of each country, must naturally have taught me to travel, and may to some extent excuse my pretension to say more on these matters than others. I have traversed a good part of Europe, and have been able to examine in detail all the formations of this continent. In spite of trying adventures, it is no mere invalid who now speaks and bids adieu to an active life, but one who, having seen much during a period of twenty years, believes that he may usefully recapitulate his observations for the benefit of his fellows, before again starting on the wandering life to which fate seems to have condemned him. The West flees from me, the East summons me; my grave shall be where heaven may please." During one of his sojourns in Paris he and a few others founded the present distinguished Geological Society of France. In a letter which I had from him at the time of the jubilee of the Society last year, he writes: "The Geological Society of France was created in my library room, April 1, 1830; present were Brongniart (Alex.), Cordier, Férussac, Blainville, Constant Prevost, Jobert—all dead. [This is not quite correctly remembered; for the meeting took place on March 17, 1830, in the rooms of the Philomathic Society of Paris, Boué himself in the chair.] They wish I should preside at this solemn meeting, but at eighty-six years of age, with my infirmities, it was impossible." He was one of the early presidents of the Society, and through life continued to take a paternal interest in its welfare.

Some forty years ago or more, after many wanderings in Austria and the adjacent countries, Boué obtained a piece of land at Vöslau, on the last spurs of the Eastern Alps, looking over the great plain which stretches eastwards to the Carpathian mountains. There were at the time few or no houses about the place, and the three or four acres acquired by Boué were a free gift from the proprietor to encourage building there. Now it is a fashionable watering-place for the Viennese, with numerous villas and hotels gathered round a copious hot spring, the water from which is caught in a swimming basin. I visited the veteran there in 1869, and found him established for the summer among his vineyards and his orchard well stocked with quinces, almonds, peaches, and apples. He had no children, but had adopted as a daughter a relative of his wife. It was charming to see the enthusiasm with which he threw himself into everything that he did. In spite of severe suffering and numerous operations of lithotomy he still retained, for an old man of seventy-five, an extraordinary vigour and vivacity. He made wine enough not only to supply his own needs, but to sell to the dealers, and looked after every detail of the process as if wine-making had all along been the only occupation of his life. He took me with him on some interesting excursions in the neighbourhood, and warm though the weather was, he walked at a pace to which even young geologists are not accustomed in this country. It was delightful, too, to listen to his reminiscences of old times. He had known most of the geologists of note of the century, and had corresponded with all of them. He had amusing little personal recollections to give, mostly in English, which he would now and then, when the words failed him, exchange for German. He remembered down to the minutest details his life at Edinburgh and his rambles in Scotland. Now and then in a pause of our talk, as his memory drifted back again into the old student days, his face would lighten up with a sudden gleam of satisfaction as he would question me as to some quarry or brook-section he had visited more than half a century before, and which stood out as distinctly as if it were again in front of him. At his town house in Vienna, whither he used to return for the winter, he showed me his tabulated geological indices, in which he said that every geological work or memoir published in his time in every language was catalogued. It is much to be desired that these indices, which were carefully written out by himself, should be promptly published. They are particularly full, I believe, in the department of physical geology. Up to the last he retained his interest in the progress of the science, and communicated thoughtful papers on the work of others when no longer able to make original researches himself. The many long letters he wrote to me were always full of gossip as to the doings of his friends in Vienna, and shrewd remarks on passing events, scientific or otherwise. They were always in English, as I have said, but often with such strange idioms and spelling as occasionally made their meaning not very clear. I am tempted to give a quotation from one which I received from him in November, 1870, during the time of the Franco-German war:—"I was retain to late in the country this year by bad weather. My vintage did protract itself so late in October that we are hardly established comfortably now in town. Besides, the dreadful war preoccupations did take me all time from thinking at scientific matter, and now perhaps that distress will approach till nearer our abode. When you will know that I have very good and near parents in both armies and you perceive the possibility of parents killing themselves without recognising themselves, nor having the opportunity to do so, you will understand that I have often headach when I ride the newspapers or hear from the quite useless slaughters which have been prevented only by those men at the head of the human Society. I have parents in Paris, other exiled in Spain in England in Switzerland. The country houses of some by Paris are German hospitals or barracks. . . . As descending from Frenchmen I fill myself quite happy to be a German and to have remain such my whole life on."

With the regret that accompanies the severance of a tie that links us with so many interesting associations of the past there mingles in no common measure the feeling of personal bereavement. Retired for so many years in his Austrian retreat, Boué kept up the freshness of his youthful sympathy with progress and the kindliness of his hearty exuberant nature. May the dust lie light on his honoured head! To have even seen his round, good-natured face and sparkling eye was something to remember with satisfaction; but to have been privileged with his friendship was an honour the recollection of which will be more than ever precious to those from whom it has now been for ever withdrawn.

ARCH. GEIKIE

NOTES

THE International Exhibition of Smoke-abating Appliances at South Kensington was opened yesterday with great *éclat*. The opening meeting was held in the Albert Hall, the Lord Mayor in the chair, supported by the Marquess and Marchioness of Lorne, Doctors Siemens and Frankland, Captain Galton,

Sir H. Thompson, Lord Aberdare, and many men of science and others interested in the movement. The following awards will be made :—A prize of 100 guineas, given by Dr. Siemens; two prizes, together of about 100 guineas, given by ladies interested in the National Health and Kyrle Societies, for the best domestic fire-grate; the Society of Arts medals; a prize of 50*l.*, given by the Manchester Association for the Prevention of Noxious Vapours, and certificates to be awarded by the Council.

THE Annual Meeting of the Royal Society was held yesterday. The usual business was transacted. Part of the President's interesting address will be found in another column.

MR. H. N. MOSELEY, F.R.S., has been elected to the Linacre Chair of Physiology in the University of Oxford, vacant by the death of Prof. Rolleston. We heartily congratulate Prof. Moseley and the University of Oxford, whose appointment must be regarded with genuine satisfaction.

BARON NORDENSKJÖLD was in town for a few days last week, leaving again on Sunday, much to the disappointment of many who wished to make up for the poor reception he met with when he called here on his way home round Europe and Asia. It will be remembered that he reached London on a Good Friday, when no one expected him, and when we were in the throes of an exciting parliamentary election. His present visit was therefore looked forward to as affording an opportunity of showing worthily England's appreciation of his great work. Unfortunately, however, he was compelled to leave before anything could be done. Baron Nordenskjöld's narrative of his great voyage will be published in a very few days, and will, we believe, besides describing the incidents and discoveries of his own voyage, contain a narrative of research on the northern shores of Europe and Asia from the earliest times down to the present day. Its scientific value is likely to be very great.

IN consequence of an appeal from Mr. Leigh Smith's relations and friends, the Council of the Geographical Society on Monday last resolved to ask the First Lord of the Admiralty to receive a deputation from their body, accompanied by experienced Arctic navigators, who will urge upon him the necessity for taking immediate steps for the relief of the *Eira*. It is considered by Mr. Smith's friends that a well-equipped and commanded steamer alone can meet the requirements of the case, as it is not impossible that the *Eira* may have met with some serious disaster, and that it would certainly be necessary to visit without delay Eira Harbour and other points on the south coast of Franz-Josef Land. Perhaps a more modest request that two or three gunboats should at once be ordered to cruise up and down the ice-limit during the winter, and keep a bright look in all directions, might receive more attention, and would in the end probably prove as effective, and certainly less dangerous than the other plan. The *Eira* left Peterhead in the middle of June, and appears to have been only once spoken, viz. by the Norwegian vessel *Proven*. She first met the *Eira* on June 30, steering for the Matyushin Shar, and eight days later met her again steering a northerly course. It may fairly be assumed, therefore, that in the mean time Mr. Leigh Smith had made an ineffectual attempt to pass through the strait.

IN his report for the present year General W. B. Hazen, Chief Signal Officer of the United States, makes some useful remarks on International Polar research. From the progress made by the Signal Corps in the study of meteorology in late years, it has become clear that, owing to the very mobile nature of the atmosphere, the changes taking place in one portion of the globe—especially the Arctic zone—quickly affect very distant regions. The study of the weather cannot be properly carried on without a daily map of the whole of the northern hemisphere, and the great blank space of the Arctic region has long been a source of regret. General Hazen was, therefore, glad to co-operate in the work of the International Committee on Polar Research in their project for forming Arctic and Antarctic Stations. Their general object will be to accomplish by observations made in concert at numerous points such additions to our knowledge as cannot be acquired by isolated or desultory travelling parties. No special attempt will, he says, be made at geographical exploration, nor will there be any endeavour to reach the North Pole. The U.S. Signal Service undertook to organise two of these expeditions this year, one of which, as we know, was safely established under Lieut. Greely, in August last, at Discovery Harbour, Lady Franklin Bay, and we are glad to be able to announce that the other, under Lieut. Ray, was left in safety at Point Barrow on September 17 by the *Golden Fleece*, in which vessel it had been conveyed from San Francisco. The position of the former station, we may add, is in N. lat. 81° 40′, W. long. 64° 30′.

ON Monday last an unusually interesting paper was read before the Geographical Society by Mr. E. C. Hore of Ujiji, on his experiences in East Central Africa, and more particularly on Lake Tanganyika. His knowledge of Lake Tanganyika is unrivalled, as he has examined it carefully along its whole coast-line of some 900 miles, and he has crossed it in various parts. His description of the River Lofu, at the southern end, was very effective, and the same remark applies to the scenery of various parts of the lake-shore. Mr. Hore says that there are ten tribes living along its coast region, and he referred to their industries, including peculiar modes of fishing, and the species of co-operation among them which raised them far above the level of the natives on the sea-coast. He mentioned a number of the products of the country, among which are various kinds of timber used for making canoes, spear-heads, &c. Two species of crocodile are found in the lake, and Mr. Hore created some amusement by saying that Stanley's water-hyænas, on investigation, turned out to be otters. Owing to the singular formation of the lake, its depth is a matter of some interest; but all Mr. Hore can say is that he could obtain no bottom with about 170 fathoms of line. Among the other matters dealt with were visits to the Lukuga outlet of the lake, the current of which has lately got much slacker, and the Malagarasi, one of the largest rivers emptying into the lake. At Mr. Hore's first visit the latter was 500 feet broad, with a swift current and rapids five and a half miles from its mouth. On subsequent visits the channel was found comparatively empty, a result largely brought about by the lowering of the lake level.

MR. E. C. HORE has presented to the Geographical Society the map of Lake Tanganyika which he constructed from careful surveys and observations made during his various explorations, the results of which he described in his paper above referred to.

M. PLATEAU describes as "*un petit amusement*" the following experiment :—A flower like a lily, with six petals each about an inch long, was constructed in outline in thin iron wire; the wire being first slightly peroxidised by dipping for an instant into nitric acid. This wire frame was then dipped into a glyceric-soap-solution, which, when it was withdrawn, left soap-films over the petals. The stalk was then set upright in a support, and it was covered by a bell-glass to protect it from air-currents. In a few moments the most beautiful colours made their appearance. If the solution is in good condition the films will last for hours, giving a perpetual play of colour over the flower.

THE stories which we have from time to time heard respecting an alleged discovery of relics and journals of the long-lost explorer, Dr. Ludwig Leichhardt, and upon which discredit has lately been thrown, would appear to have some foundation after all, for by the last Australian mail news has been received that

the New South Wales Government have agreed to the somewhat exorbitant demands of the bushman, Mr. J. R. Skuthorpe, and will give him 6000*l*. for the relics, &c., provided their genuineness be established by certain tests. Mr. Skuthorpe has now no excuse for keeping his alleged "find" buried in the far interior, and it cannot be long before the matter will be settled one way or the other. Mr. Skuthorpe is stated to have given an outline of the contents of the journals, among which are accounts by Classen of Dr. Leichhardt's death and his own life among the natives.

PROF. HAECKEL is at present in Ceylon, where he is to stay for three months for a scientific exploration of the island.

THE German Government is considering the participation of German men of science in the plan of International Polar Research. The Reichstag has been asked to grant the necessary funds, which are fixed at 300,000 marks (15,000*l*.). Besides this sum 180,000 marks (9000*l*.) are asked for the Transit of Venus Expedition in 1882, and 75,000 marks (3750*l*.) for expeditions to Central Africa.

THE forthcoming lecture arrangements at the Royal Institution will include the usual Christmas course of six lectures, to be given this year by Prof. R. S. Ball, the Astronomer-Royal of Ireland, on the Sun, Moon, and Planets (with illustrations by the electric light, &c.). Eleven lectures by the new Fullerian Professor of Physiology; four lectures by Prof. H. N. Moseley on Corals; four lectures by Dr. P. L. Sclater on the Geographical Distribution of Animals; three lectures by Prof. Tyndall; four lectures by Prof. Pauer on Louis van Beethoven (with illustrations on the pianoforte); four lectures by Mr. W. Watkin Lloyd on the Iliad and Odyssey. The Friday evening meetings will begin on January 20 at 8 p.m. Dr. W. Huggins will give a discourse on Comets. Succeeding discourses will probably be given by Mr. R. S. Poole, Professors Odling, Frankland, J. G. M'Kendrick, and W. E. Ayrton, Capt. Abney, Mr. A. Tylor, Mr. J. W. Swan, Mr. W. Spottiswoode, and other gentlemen. Mr. H. H. Statham's four lectures on Ornament, delivered at the Royal Institution, are to appear in the Portfolio for January and following months.

PREPARATIONS are being made in Edinburgh for the celebration of the centenary of Sir David Brewster's birth next month.

MR. EDISON has entered the field of competitors in the construction of storage batteries for electric currents. His particular method of storing currents has however not yet been made public.

THE *Daily News* Naples correspondent writes that a small party of travellers is proceeding to India, one of whom is Paolo Mantegazza, the organiser of the expedition, the object of which is, on his part, to make anthropological studies of the Indian races, and to collect skulls and bones for the Museum at Florence. One of his companions, Signor Fabricotti, a naturalist, will collect animals and plants, and the other, Signor Michela, an artist, will reproduce or copy the antique Indian ornamentation of the monuments, china and bronzes, that adorn Indian temples and houses. Signor Mantegazza is particularly interested in the races of the Himalaya, and, after a general survey of India, it is to this region that the attention of himself and of his companions will be especially devoted.

HERR J. N. AROSENIUS gives in the last number of the *Zeitschrift für die wissenschaftliche Geographie* (vol. ii. fascicule 5), an account of the ethnographical frontier between Finns and Swedes in Northern Sweden. This frontier does not coincide either with the old one, which ran along the range of hills between the Torneo and Kemi rivers, or with the present one which runs along the Torneo. It begins on the shore of the Gulf of Bothnia, between the post stations Sangits and Säivits, and runs straight north to the Kengis iron-works. But some three or four hundred miles south-west of this frontier there are in Sweden numerous small patches inhabited by Finns, which patches make a broken chain going from the Wermland to the Medelpad province. The flat land and the valleys altogether are inhabited by Swedes, but nearly everywhere in the most remote parts of the forest are to be found one or several Finnish houses, built in the old Finnish fashion. Isolated in the wilds, Finnish people in Sweden gradually forget their former language, and mostly speak Swedish, especially after having reached a certain age. In the province of Dalarne the Finnish language is quite forgotten by the Finns, and their origin can be discovered only by their customs, dwellings, and by very few remains of their former language; thus M. Arosenius has seen a woman who knew only a single Finnish sentence, one of the most frequently used, however, "Light me the pipe." As to the remains of Finnish population in the province of Smaland, the question still remains open; but it is proved that there are remains of two different peoples, one of which must have been of Lapp origin, whilst the other, which knew the use of bronze implements and agriculture, must have been, M. Arosenius thinks, Finnish.

DON JUSTO ZARAGOZA contributes to the *Boletin* of the Geographical Society of Madrid a series of interesting papers on ancient canal schemes between the Atlantic and the Pacific in Central America. There were three places which the Spanish of the sixteenth century thought of for these schemes: the isthmus of Tehuantepec in New Spain, now Mexico; the river of San Juan, of the Lake of Nicaragua, in the republic of the same name; and the Chagre River, and other parts of the Isthmus of Panama. The investigation of Tehuantepec was abandoned at that time, to be renewed in our century; those of Nicaragua were actively pursued in the seventeenth century, and were nearly being executed about the middle of the eighteenth century, during the reign of Charles III., and the scheme of a canal through the Isthmus of Panama, also abandoned, has now been renewed by M. Lesseps. In the paper published in the October number of the *Boletin* D. Zaragoza gives interesting information on the little-known scheme of a canal *viâ* the Lake of Nicaragua, which scheme appeared in the year 1548, with a map of the land prepared by Arias Gonzalo. In 1606 Captain Ochoa de Leguizamo explored, on the same account, the Puertos de Caballos and Fonseca Bay; and during the years 1780 to 1783 a map of the projected canal, still existing, was prepared, and a survey was made between the Pacific and the Lake of Nicaragua, which last proved to be 133 Castilian feet above the sea-level, the height of the water-shed being 604 feet. This scheme met with great opposition, the chief reason for which was found in the statement of Juan Bautista Antonelli, an engineer sent by Philip II., who declared the scheme quite impracticable; and D. Zaragoza publishes an interesting memoir, by J. Antonio de Escartin, to prove the possibility of the canal. The paper will be continued.

PROF. A. H. CHURCH gives a course of lectures on Chemistry at the Royal Academy of Arts on December 2, 7, 9, 12, 14, and 16; of course the lectures will have special reference to the bearing of Chemistry on Art.

ADMIRAL MOUCHEZ is continuing with vigour the completion of his astronomical museum. Eight oil paintings have been placed in the foreign astronomers' room, representing respectively Copernicus, Tycho Brahé, Galileo, Kepler, Huyghens, Newton, Bradley, and J. Herschel. A large number of engravings and photographs, representing either celebrated astronomers, large instruments, or foreign observatories, have been collected in the same room.

A VERY hopeful Report has been published by the Winchester College Natural History Society. This is its Fifth Report, though the Society has been in existence ten years. It has not been thought necessary to publish any account of the doings of the Society for five years, though we are assured that it has been none the less doing good work. This is what is wanted, and the present report bears evidence that the Winchester Society is in a healthy and fairly vigorous condition. The sectional reports are good, and the Society has formed some very fair collections.

THE Berlin Philosophical Society, founded in 1843 by the disciples of Hegel, but now numbering amongst its members men of the most various philosophical creeds, has applied the surplus of funds recently collected for a monument in memory of Hegel to the foundation of a Hegel Institution, the object of which is the furtherance of philosophical research. The Society has just issued the following prize theme: "A critical and historical account of the dialectical method of Hegel." The treatises may be written either in German, French or English, and must be sent in before December 31, 1883. The prize is 450 marks (22*l.*).

A NEW natural history serial will soon be published by Enke of Stuttgart. Its editor is Dr. Georg Krebs of Frankfort on the Maine, and its title, *Humboldt, Monatsschrift für die gesammten Naturwissenschaften.*

THE "Encyklopædie der Naturwissenschaften," published by Trewendt of Breslau, is now well advanced. Part 25 contains the seventh instalment of the Dictionary of Zoology, Anthropology, and Ethnology, and only brings it down to *Distoma.* Parts 26 and 27 contain the eleventh and twelfth (the concluding) instalment of the Handbook of Mathematics.

DR. NAGORSKY, having measured the capacities of lungs of 630 boys and 314 girls in the schools of the district of St. Petersburg, now publishes the results of his investigation in a Russian medical paper, the *Surgeon.* He has found that the capacity of lungs, in relation to the weight of the body, is 65 cubic centimetres for each kilogramme of weight in boys, and 57 cubic centimetres for girls. The law of Quetelet being that with children below fifteen years of age, the weight of the body is proportionate to the square of the height, Dr. Nagorsky has found that it is proportional to 2·15 of the same; whilst the capacity of lungs is proportional to 2·4th of the height for boys, and to the square of the height for girls. Dr. Nagorsky's researches will soon be published as a separate work. As to the relation between the weight of man and the capacity of lungs, it is tolerably permanent, and its variations are mostly due to differences in the amount of fat in the bodies of different men.

IN our article on the Geological Congress (NATURE, November 10) in the table of terms, in the first column of p. 35, the word *Cycle* should be *Ère* (*era*).

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. R. M. Edger; a Blackbird (*Turdus merula*), two Song Thrushes (*Turdus musicus*), a Starling (*Sturnus vulgaris*), two Skylarks (*Alauda arvensis*), a Greenfinch (*Ligurnis chloris*), two Chaffinches (*Fringilla cælebs*), two Common Quails (*Coturnix communis*), British, presented by Mr. Edward Lawrence; a Black-winged Peafowl (*Pavo nigripennis*) from Cochin China, presented by Mr. J. Marshall; a Common Kestrel (*Tinnunculus alaudarius*), British, presented by Mr. A. Lidbury; a Grecian Ibex (*Capra ægagrus*) from South-East Europe, four Orange-cheeked Waxbills (*Estrelda melpoda*), two Common Waxbills (*Estrelda cinerea*) from West Africa, two Maja Finches (*Munia maja*) from Malacca, a Black-headed Finch (*Munia malacca*), an Indian Silver-bill (*Munia malabarica*) from India, a Song Thrush (*Turdus musicus*), British), a Blue-crowned Parrakeet (*Tanygnathus luzonensis*) from the Philippines, a White-eared Conure (*Conurus leucotis*) from Brazil, deposited; a Bar-tailed Godwit (*Limosa lapponica*), two Razorbills (*Alca torda*), two Common Lapwings (*Vanellus cristatus*), two Golden Plovers (*Charadrius pluvialis*), two Knots (*Tringa canutus*), a Red-throated Diver (*Colymbus septentrionalis*), British, purchased; a Spotted Ichneumon (*Herpestes auropunctatus*) from Nepal, a Geoffroy's Dove (*Peristera geoffroii*), two Brazilian Teal (*Querquedula brasiliensis*) from South America, two Mandarin Ducks (*Aix galericulata*) from China, received in exchange.

OUR ASTRONOMICAL COLUMN

THE SATURNIAN SYSTEM.—In a memoir published in t. xxvii. 2^me partie, of *Mémoires de la Société de Physique et d'Histoire Naturelle de Genève*, entitled "Recherches sur Saturne, ses Anneaux et ses Satellites," M. Wilhelm Meyer, assistant-astronomer at the Observatory of Geneva, presents results of his observations made with the 10-inch refractor, the gift of Prof Plantamour to the establishment, during the opposition of 1880. They consist of measures of the rings and equatorial and polar diameters and observations of the satellites Enceladus, Tethys, Dione, Rhea, and Titan, with elements deduced from them. M. Meyer was not certain that he had observed Mimas in 1880, but in a note he mentions that on the night of September 4, 1881, which was "une des plus belles, quant à la diaphanité de l'atmosphère," he obtained an undoubted observation of it; at 13h. 13m. 27s. Greenwich mean time it was distant 31″·1 from the centre of Saturn, exactly in the plane of the ring on the preceding side, or, as he expresses it, $x = -31''{\cdot}1$, $y = 0$.

For the outer diameter of ring A he finds 40″·47 for the mean distance of Saturn, which, like other measures with the filar-micrometer (employed for all the measures at Geneva) is in excess of the results given by the double-image micrometer; Kaiser found the outer diameter with the latter 39″·47. Considering the difficulties attending measures of this class with the filar-micrometer, preference, no doubt, is to be given to the double-image principle, though without much practice there may be a tendency to *clip* the measures made with the instrument. If it were preferred to take something like a general mean of the reliable measures to this time, the outer diameter of the ring would be found to differ little from 39″·75.

M. Meyer has referred all his times to the meridian of Greenwich, because, as he says, it is that adopted by Mr. Marth in the calculation of his elaborate ephemerides of the satellites, to which he acknowledges his obligations.

We subjoin the elements of the four satellites interior to Titan which were measured at Geneva:—

	ENCELADUS	TETHYS	DIONE	RHEA
Epoch	Oct 8·0 ...	Oct. 27·0 ...	Oct. 27·0 ...	Oct. 27·0
	° ′	° ′	° ′	° ′
Mean long.	5 18·3 ...	300 2·2 ...	155 5·2 ...	309 42·9
Peri-Saturnium ...	181 45·3 ...	204 6·8 ...	180 16·8 ...	239 26·0
Node	127 5·9 ...	113 57·6 ...	124 17·0 ...	127 4·5
Inclination	4 38·0 ...	7 0·7 ...	6 41·5 ...	6 36·2
Eccentricity	0·066235 ...	0·006847 ...	0·016888 ...	0·014657
	″	″	″	″
Semi-axis major ...	34·29 ...	42·48 ...	54·58 ...	75·97
	d. h. m. s.	d. h. m. s.	d. h. m. s.	d. h. m. s.
Tropical revolution	1 8 52 40·5 ...	1 21 18 8·4 ...	2 17 40 54·1 ...	4 12 25 25·4

The node and inclination are referred to the plane of the terrestrial equator.

The separate values of the mass of Saturn which M. Meyer deduces from his observations are discordant.

THE LUNAR ECLIPSE ON DECEMBER 5.—The eclipse of the moon next Monday evening, though very nearly total, will not be actually so, the magnitude being 0·973. The first contact with the shadow occurs at 3h. 28m., but the moon does not rise at Greenwich till 3h. 50m. The middle of the eclipse occurs at 5h. 8m., and the last contact with shadow at 6h. 49m. The shadow enters upon the moon's surface at about 60° from the N. point of the limb towards the east. The fifth magnitude star ι Tauri is occulted at Greenwich at 6h. 23m., before the shadow is off the disk.

On October 13, 1856, there was a lunar eclipse of similar character, magnitude 0·994.

VARIABLE STARS.—R Leporis. According to Dr. Julius Schmidt's observations during the interval 1865–1875, the mean

period of this variable appears to be about $436\frac{1}{2}$ days, and a maximum may be expected about January 19, 1882; its magnitude at maximum has been estimated 6·5 by Schmidt and 6 by Gould; at minimum it is about 8·5. Observations of the degree of intensity of colour in this "crimson star" are desirable, as there are indications that it has varied with variation in brightness. At times it has been recorded that the red colour was not particularly striking, whereas at the first observation of this star in October 1845 it arrested attention whilst comet-sweeping. (2) R. Draconis. Dr. Schmidt noted a maximum on April 22 in the present year, or 251 days after the preceding one, so that another maximum may be looked for about December 29. The star is Lalande 30387, and its variability was detected at Christiania; the position for 1882·0 is in R.A. 16h. 32m. 20s. Decl. + 67° 0'·1; it is followed by a star 8·9m. (L 30413) by 53s., 1'·5 to the south of it. Prof. Pickering's suspected variable of 1881, September 13, is about $5\frac{1}{2}$° to the north; R.A. 16h. 31m. 32s., Decl. + 72° 32'; it is "red, spectrum-banded."

(3) μ Cephei (Bayer) is probably now on the increase, but we do not find very recent observations; the position of this "garnet-sidus" for 1882·0 is in R.A. 21h. 39m. 53·7s., Decl. + 58° 14' 21"; Argelander's mean period is 432 days, Prof. Schönfeld calls it "irregular."

THE ROYAL SOCIETY—ADDRESS OF THE PRESIDENT

ON the occasions of our anniversary our first glance is usually retrospective, in memory of those once among our numbers, but now surviving only in their works. On our home list we have this year lost more than a score of Fellows. On the foreign list we have lost but one; that loss will however be severely, if not so widely, felt.

In Michael Chasles mathematicians recognise a geometer of unusual powers, who, having devoted a long life to his favourite study, has left an extensive and characteristic train of researches behind him. But a larger circle of friends recognised in him a great and good man, beloved by all who knew him, and respected beyond the range of his personal acquaintance. As a pure geometer he belonged to a class of mathematicians for which the Academy of Sciences of Paris has long been justly celebrated; but whose numbers appear liable to a perceptible fluctuation, perhaps partly owing to the brilliant opportunities and the varied fascinations which modern algebra offers to the student. Eminent in a nation which has always been intolerant of obscurity in science, he showed in a remarkable degree how much might be elicited through precision of thought and by clearness of exposition from a few well-selected and fertile ideas. Such, for instance, proved to be the consideration of Anharmonic Ratios, the principle of Correspondence, and the method of Characteristics. Whether in the latter he had struck a vein so completely out of the range of the analyst, as he himself supposed, may perhaps be still claimed as an open question; but certain it is that he showed the fertility of the method by continuing to deduce from it an apparently inexhaustible flow of theorems, even after the more serious part of his mathematical work had been done. And there is little doubt that long after the time when many subsequent works have fulfilled their purpose, and have fallen into a natural oblivion, his "Aperçu Historique," his "Géométrie Supérieure," and the fragment of his "Traité des Sections Coniques," will be regarded as classics in the library of the mathematician.

Turning to the home list, the remark made in my last address, viz. that our losses had been mainly among our older Fellows, might be repeated with even more emphasis on the present occasion. Of the twenty-two who have died during the intervening period nine had reached the age of three score and ten, eight that of four score, and one, Dr. Billing, had attained his ninety-first year.

In Lord Beaconsfield and Sir James Colvile we have lost two distinguished members, elected under the statute which gave a new definition of the privileged class a few years ago. Lord Hatherley will be recollected as having served on our Council within recent years, and as having often given us very useful advice on subjects requiring the sound judgment of an experienced mind. Although Lord Hatherley would doubtless have been elected, as a member of the Privy Council, under the statute above mentioned, it is perhaps worth remark that he was elected under statute previously existing, and that his fellowship dated from the year 1833.

The late Dean of Westminster furnishes another instance of the wise exercise of a power which the Royal Society has always reserved to itself, notwithstanding the changes made in 1847, of electing from time to time men of eminent distinction in other avocations of life than those of strict science. Of Dr. Stanley's attainments and merits in those other directions it is not my province to speak; and, indeed, it is the less necessary that I should do so, for they were so many and so varied that in one way or other they were known to all. But he was conspicuous, both among the members of his own profession and among many others who have neither predilection nor training for actual science, for his genuine and honest sympathy with its principles and its objects, and with the labours of those who cultivate it.

In Dr. Lloyd, whose age was coeval with the century, and who was a fellow-worker with Herschel, Whewell, Peacock, and Sir W. R. Hamilton, we seem to have lost one of the links which connected us with a past generation. While himself no mean mathematician, he was distinguished especially in the sciences of optics and of magnetism. In the subject of optics he had the rare opportunity of supplying the experimental verification of Sir W. R. Hamilton's brilliant geometrical conclusions on the configuration of the wave-surface; and it was largely due to his patience, his delicacy of touch, and his almost instinctive sagacity, that the phenomena of conical refraction were first made visible to the human eye. In magnetism he assisted in the formation of the great survey of the globe, initiated by Sir E. Sabine, and as director of a magnetic observatory in Dublin he made valuable contributions to the subject. His scientific remains, brought together in one volume, have been a welcome addition to the library both of the mathematician and of the experimentalist. His interest in science and in its promoters was active throughout his long life; and those on whom the honorary degree of LL.D. was conferred at the late meeting of the British Association in Dublin, will always cherish as a pleasant reminiscence the fact of having received it at his hands.

Dr. Bigsby was one of the earlier cultivators of Geology. Some of his first studies were made at a time when the subject was hardly a science; but in attaining the advanced age of eighty-nine he lived to see it what it has since become. He founded a medal at the Geological Society, of which he was for many years a member.

We are again reminded of the progress which has been made in science, and in the cultivation of it during the present generation, by the fact that until the last day of last year we could reckon among our Fellows Dr. John Stenhouse, one of the surviving founders of the Chemical Society.

On the subject of our property there is little change to report. Further investments have been made in due course on account of the Fees Reduction Fund. The sale of the Acton estate has not yet been completed, but a deposit is in hand, and a half year's interest on the balance has been received.

The Charitable Trusts Bill, which was introduced into Parliament last session, and which would have affected our interests had it not been for a clause introduced by our Fellow the Marquis of Salisbury, specially exempting the Royal Society from its operation, was withdrawn.

The collection of portraits in the possession of the Society has been enriched by the addition of a portrait of Sir Joseph Dalton Hooker, painted by John Collier, Esq., at the expense of a considerable number of our Fellows, who were desirous of expressing their sense of the important services rendered by Sir Joseph to the Society, and at the same time of securing a permanent memorial of their late president. It is to be hoped that advantage may be taken of any suitable occasions that may arise from time to time of adding to our gallery of historical records of the great men whom we have reckoned among our Fellows.

The Fellows will learn with satisfaction that the first part of the new edition of our library catalogue is published. This part, consisting of 232 pages, contains the *Transactions*, *Proceedings*, and *Journals* published by societies and institutions in nearly all parts of the world; and also the observations, reports, and accounts of surveys which are to be found in our library. As our Library Committee has always devoted great attention to securing by exchange or by purchase publications of this class, and as the main strength of our library consequently lies in our collection of them, the part in question will form the most important section of the entire catalogue.

[1] Address of William Spottiswoode, D.C.L., LL.D., the president, delivered at the anniversary meeting of the Royal Society on Wednesday, November 30, 1881.

Progress has also been made in the more voluminous portion of the catalogue, viz. that of the general collection of scientific books, of which thirteen sheets, extending to the end of the letter C, are printed off, or are in type; and subsequent titles are in type. It may fairly be hoped that before our next anniversary the whole will be published.

The last part of the *Philosophical Transactions* for 1880 was published in March of the present year, completing a volume of nearly 1100 pages, with upwards of fifty plates. Of the *Transactions* for 1881, Parts I. and II. have already appeared; from which an early publication of Part III. may be anticipated.

Of the *Proceedings*, vol. 31 was published in June, and vol. 32 at the end of October.

Although, as I remarked last year, we are more concerned with the quality than with the quantity of the communications made to the Society, it may still be interesting to carry on the table of the number of papers presented per annum to a tenth year. It stands as follows:—

1872	99 papers received.
1873	92 ,, ,,
1874	98 ,, ,,
1875	88 ,, ,,
1876	113 ,, ,,
1877	97 ,, ,,
1878	110 ,, ,,
1879	118 ,, ,,
1880	123 ,, ,,
1881	127 ,, ,,

These 127 papers include one from Mr. Brooks of Baltimore, two from Prof. Helmholtz, and one from Capt. Mannheim, of the École Polytechnique, Paris. On reference to the papers themselves it will be noticed that several prominent men are carrying on with vigour the series of researches on which they have been, in some cases for years, engaged. Among them there may be mentioned, in physics, those of Professors Liveing and Dewar, and of Mr. Lockyer, on the Spectra of Terrestrial Substances and of the Sun; those of Prof. Hughes on Minute Interactions of Electric Currents and Magnetism; those of Mr. Crookes on High Vacua; and those of Mr. H. Tomlinson on the effect of Stress and Strain on the action of Physical Forces. Mr. G. H. Darwin continues his already classical memoirs on the mechanical history of the solar system; and Capt. Abney has opened out to view, by photographic means of his own invention, a part of the spectrum of the sun and of other bodies, beyond the red, hitherto invisible; and last, but not least, Prof. Tyndall in his Bakerian Lecture has given an account of his researches on the action of Free Molecules on Radiant Heat, and its Conversion thereby into Sound. In Biology I may mention the investigations of Mr. Romanes on nerve systems; those of Prof. Ferrier on the connection between special portions of the brain and special motor organs of the animal system; those of Mr. Parker on the Skull of the Batrachia, and of Prof. W. C. Williamson on the fossil plants of the Coal-measures. Among the newer subjects, the experiments of Dr. Young and Prof. George Forbes on the velocity of light of different colours have naturally arrested considerable attention for several reasons, and especially because the conclusions thence deduced, if ultimately established, would fundamentally modify our views of the constitution of the luminiferous ether.

For several years past I have been able with much satisfaction to report that there had been no change in the staff of officers of the Society. I much wish that I could have done so again. But the longer a capable man lives and is available, the more will work accumulate on his hands; and the time at last comes when something must be given up, lest, in the multiplication of avocations, powers which might otherwise have been devoted to some great and good purpose, and on operations not within the grasp of every one, should become dissipated among a variety of objects. A feeling that life must not be spent merely in running hither and thither, and a desire that it should be something better than a mere feat of mental agility exhibited in passing rapidly from one occupation to another, doubtless operated in leading Sir Joseph Hooker to resign the presidentship; and a similar feeling has recently led to the resignation of the secretaryship by Prof. Huxley. That this loss is great will be felt by every Fellow of the Society; it will be more keenly felt by his brother secretaries and the treasurer, but most of all by your president. Connected as I have been with him through a series of years by ties of office in the Society, by bonds of friendship and trust as thorough as can exist between man and man, I cannot but miss for a long time to come his ever willing support, his sound counsel and advice, and the cheery manfulness with which he would always address himself to any business, however difficult, uninviting, or heavy.

The post is one which it is not easy to fill. Many qualifications go to make up a good secretary; and although none of us so "despaired of the republic" as to doubt that a good successor would be found, we still felt some anxiety until we were in a position confidently to recommend a name for your consideration. Prof. Michael Foster's great scientific attainments, his administrative powers as shown in founding the great School of Biology at Cambridge, the confidence with which he inspires all around him, alike point him out as a man eminently fitted for the post. It would indeed have been agreeable to your president to have had one of the principal secretaries resident in London; but the means of communication are now so different from what they formerly were that questions of distance almost disappear; and it is certainly not without its advantages that the two principal secretaries, if not resident in London, should reside in the same city.

In the course of the spring of the present year Sir Joseph Copley, the present representative of the Founder of the Copley Memorial, explained in a visit to the president his wish to "provide in perpetuity an annual bonus of 50*l*. a year, to be given to the recipient of the Copley Medal." As the donor's views on the terms of the gift were completely made up, and were not offered for discussion by the Society, or otherwise open to modification, the Council decided to accept the offer in the spirit in which it was made, and on the terms prescribed. In accordance with this, Sir Joseph transferred a sum in Consols sufficient to provide for the bonus proposed. This acceptance will not in any way affect the adjudication of the Medal, nor, it is to be hoped, the high estimation in which that award has always been held.

The period of five years during which the experiment of the Government Fund of 4000*l*. per annum was to be tried has now expired. In a former address I have expressed opinions gathered from many of the Fellows of the Society, and have indicated my own. The President and Council have now, at the request of the Department of Science and Art, through which the vote is made, drawn up a report on the question, based upon the experience gained up to the present time, and have made suggestions with a view to a modified arrangement for the future. The Society will be duly informed of the result of those communications. In the mean time it may not be out of place to remind the Fellows that a statement of all grants made within the year is published in the report of our anniversary proceedings.

The report of the *Challenger* Expedition, of which mention was made last year, is in the course of publication; and three volumes have now appeared. Copies of these have been presented by the Treasury to our library. Vols. ii. and iii. refer to the curious forms of life found in what Sir Wyville Thomson has called the "Abysmal Region," and are copiously illustrated with lithographs. The interest which attaches to this publication is evinced by the fact that the first edition of the second volume is already exhausted. A second edition of it is in the course of printing. The Fellows will doubtless have observed that the printing of the text and the execution of the plates are maintained at the same high standard as that exhibited at the outset.

Among other scientific publications of the year, I may mention the third volume of Roscoe and Schorlemmer's work on Chemistry; Mr. Balfour's on Embryology; and Mr. Darwin's on Vegetable Mould.

In December last the Council authorised the loan of the *Philosophical Transactions* from one of our complete sets, five volumes at a time, to the Delegates of the Oxford University Press, for the preparation of a Philological English Dictionary, under the editorship of Dr. Murray. It is hoped that this loan will contribute to the completeness of the work in respect of scientific terms. Forty-one volumes have been already utilised in this way.

Towards the close of last session a communication was received from the India Office inclosing a copy of a report and memorandum, on Pendulum Observations, by Major Herschel, and asking the advice of the President and Council thereon. Subsequently there followed another communication from the same office, inclosing a copy of a letter from the same officer, with an extract from a letter to him from Mr. Peirce of the United States Coast Survey. These documents were referred

to a Committee consisting of Sir George Airy, Prof. J. C. Adams, and Prof. Stokes.

The Report of that Committee was forwarded to the India Office; the following extracts from it contain those parts which refer to the main scientific questions raised:—

"The object in referring these documents to the Royal Society was to assist the India Department in coming to a conclusion as to what, if anything, might yet be required in order to render the pendulum operations which have been carried out in connection with the great trigonometrical survey of India reasonably complete as an important contribution towards the determination of gravity all over the earth.

"At present the stations which have been directly connected with the Indian stations are confined to Aden, Ismaïlia in Egypt, and Kew; and no one of these has been differentially connected with any of the chains of stations that have hitherto been used in the determination in this way of the figure of the earth, though Kew is now a station at which an absolute determination has been made. We think it would be a reasonable expectation on the part of the scientific public that the Indian group of stations, which have already been connected with Kew, should be differentially connected with at least one chain of stations which are so connected with one another, and which have been employed in the determination of the figure of the earth.

"We approve accordingly of the suggestion that gravity at Kew should be compared, by means of invariable pendulums, with gravity at another station belonging to another group. Greenwich has been named as such a station.

"In connection with this subject, we would refer to the suggestion, which has been brought before us, made by Mr. Peirce, of the United States Coast Survey, that Major Herschel should swing the same two pendulums that were used in India, first at Kew and then at Washington.

"As Washington is, or shortly will be, connected differentially with a large chain of stations widely distributed in America and elsewhere, we think that the value of the Indian series would be decidedly increased by being connected with one of the American stations, such as Washington. We think, however, that its connection through Kew with one of the older series should not on that account be omitted.

"The observations required for the purpose of these connections are such as certainly can be made, and have been made, by existing methods; and the labour of making them, which will be approximately in proportion to the number of stations at which the pendulums will have to be swung, is only a fraction of that already incurred on the Indian stations, and the three which have been included in the same group with them."

In October last a letter was received from the Treasury asking the opinion of the President and Council respecting arrangements for observing the transit of Venus in 1882. Under the advice of a Committee appointed for the purpose, it was recommended that a special Committee of the Royal Society should be appointed to decide upon the observations considered essential, and to advise Her Majesty's Government as to the best method of carrying them out. In conformity with this advice, and at the request of the Treasury, a Committee was appointed to draw out a scheme of stations, and of the constitution, strength, and equipment of the observing parties, and to frame an estimate of the total cost. The Committee reported recommending the adoption of certain stations in South Africa, the West Indies, Australia, and New Zealand, and the Falkland Islands; and they at the same time added other particulars, and furnished an estimate of the whole, adopting in the main the recommendations of that Committee; the Treasury then requested the President and Council to nominate an Executive Committee, by which (accounting to the Treasury) any vote of Parliament for the purpose of these observations might be administered; and under whose advice the observers and assistants might be selected and appointed. In compliance with this request the following Fellows were nominated as an Executive Committee, viz. the President, Prof. J. C. Adams, Sir G. Airy, Mr. Hind, Sir G. Richards, Prof. H. J. Smith, and Mr. Stone. That Committee is now continuing its labours, and has appointed its member, Mr. Stone, of the Radcliffe Observatory, Oxford, directing astronomer of the expeditions; and under him the selection of instruments, as well as the training of the observers, will be made.

With a view of making the observations ultimately as comparable as possible, the Committee, at an early stage, put itself, through the Foreign Office, into communication with the corresponding Commissions in foreign countries, on the subjects of the instructions to be given to the various observers; and a draft set of instructions, drawn up for this purpose, was circulated for comment and suggestion.

Moved perhaps in some degree by this action, the Governme n of France took advantage of the assemblage of scientific men collected in Paris for the Electrical Congress and Exhibition, to summon a Congress of Astronomers, having especially in view a consensus of arrangements for the observation of the Transit. This Congress met in Paris on October 5, under the auspices of the Minister of Public Instruction. M. Dumas was appointed President; MM. Foerster and Weisse, Vice-Presidents; MM. Tisserand and Hirsch, Secretaries. The various countries of Europe were represented; but it was a matter of much regret that no representative from the United States of America was present. Mr. Stone attended on behalf of the British Committee. I must here express my regret at having been unable to attend in person to support our directing astronomer, who made the journey at much inconvenience to himself; but I should at the same time add that my absence in no way diminished the effectiveness of Mr. Stone's counsels, which proved of great service in promoting a unanimity in the views finally adopted by the Congress.

Two Committees were appointed: (1) for the selection of stations; (2) for a discussion of methods of observation.

As the British stations had been already chosen, and did not admit of material alteration, the first of these Committees did not directly concern us. But, judging from the number of observations contemplated to be made in South America by foreign expeditions, it seems not impossible that the party which we had proposed for the Falkland Islands might be advantageously transferred to some other locality, so as to strengthen the parties requiring support, for example, in Australia.

As regards the discussion of methods, the draft instructions drawn up by the British Committee, and especially the definition of contact to be observed, strongly insisted upon by Mr. Stone, were in the main adopted. The following are the principal points agreed upon:—

With a view to uniformity of method of observation it is necessary that instruments of nearly the same aperture (six inches) should be used, also that the observations of contact should be made in a field of just sufficient brightness to allow of the clear separation of two threads at one second of arc apart when seen projected on the sun with a power of 150. The times corresponding to the internal contacts should be defined as follows:—

At Ingress.—"The time of the last appearance of any well-marked and persistent discontinuity in the illumination of the apparent limb of the sun near the point of contact."

At Egress.—"The time corresponding to the first appearance of any well-marked and persistent discontinuity in the illumination of the apparent limb of the sun near the point of contact."

It is a point of primary importance that all the observers shall, as far as possible, observe the same kind of contact; and it is therefore desirable that the times recorded for contacts should refer to some marked *discontinuity* in the illumination of the sun's limb about which there cannot be a doubt, and which may be supposed to be recognisable by all the observers. If a pure geometrical contact is alone seen, there can be no doubt about the time which should be given; but, if haze is noted, it should be haze nearly as dark as the outer edge of the planet; and if a ligament is seen, it should be nearly as dark as the outer edge of the planet.

A further proposal was made to establish a Central Bureau in Paris to receive and discuss the observations, and to enter upon other work more or less directly connected with the determination of solar parallax. But, as this question was not contemplated in the instructions given to our representative, and indeed exceeded the powers of the British Committee, no definitive resolution was passed on the subject.

On the subject of the longitude of a point in Australia, to which I made allusion in my address last year, as important for the observations of the transit of Venus, I have lately received a letter from Mr. Todd, of the Observatory, Adelaide, from which the following is an extract: "With regard to the determination of Australian longitudes: as it is understood that Lieut.-Commander Green, U.S.N., will call at Port Darwin to determine its longitude by signals from Singapore on the one side, and with the Adelaide Observatory on the other, I have taken no further steps for going to Port Darwin, as previously arranged. I shall take all the necessary observations here, and

exchange signals with Lieut.-Commander Green over my overland telegraph; and, in conjunction with Messrs. Ellery and Russell, make fresh determinations of the difference of longitude between Adelaide, Melbourne, and Sydney."

Since our last anniversary, Sir George Airy, the late Astronomer Royal, having completed his eightieth year, and nearly half a century of office, has retired. Of his services to science, and to this Society as President, and in other ways, the time to speak has happily not yet arrived. His great intellectual powers are in fact in no way impaired, and so far from having brought his period of activity to a close, he hopes to employ his well-earned leisure in completing a favourite work, the Numerical Lunar Theory.

His successor, Mr. Christie, from his long experience in the Royal Observatory, will combine a thorough training in the remarkable organisation and methodical administration for which his predecessor was so conspicuous, with the full vigour of life, and an active interest in the more modern developments of astronomy, in which he is already distinguished.

The future of the Royal Observatory is a subject on which the mind of Sir George Airy often exercised itself, and to which he alluded more than once in his Reports to the Board of Visitors. With his fundamental proposition that observational astronomy, in its bearing on the improvement of navigation, must always be its main line of work, every one must agree. Over and above this, the expressed wish of the Board of Visitors, and the practice of the last few years, have already sanctioned the addition to the ancient duties of the Observatory of some of those long and systematic series of observations, such as that of the solar protuberances, and the motion of the fixed stars in the line of sight as shown by the spectroscope, which are beyond the scope of an amateur, and above the power of any individual astronomer, however devoted to his work, to permanently maintain. How far it may be desirable to continue magnetic and meteorological observations beyond the necessities of an astronomical observatory, are questions which will doubtless engage the attention of the present director. The main question must be, What distribution of these branches of study among Greenwich, Kew, and other establishments, will in the end best conduce to the progress of science? And with a view of giving full scope to the judgment and skill of the present and future holders of the office the Board of Admiralty have, as I understand, decided to consider a revision of the terms of the Royal Warrant under which the appointment is made.

This year has been signalised by the meeting of a most important scientific congress—the International Congress of Electricians, held at Paris. The recent developments of the practical applications of electricity rendered the occasion favourable both for organising a special exhibition devoted solely to this branch of science, and also for assembling the electricians of all countries.

The general purpose of this Congress was to discuss, and if possible to settle, some of the numerous difficulties which perplex both the physicist in his studies and the constructor in his work.

But chief among the subjects proposed to, and undertaken by, the Congress was that of fixing a system of electrical measures for international adoption.

Perhaps in no subject is the necessity of uniform system of standards so striking as in electricity. This science, both in its practical applications, such as telegraphy, and in the great natural problems of terrestrial magnetism and atmospheric electricity, refuses to recognise any artificial divisions of the surface of the globe, whether ethnological or political. It rarely happens, in operations undertaken on so large a scale as the study of electricity and its industrial applications, that an opportunity presents itself of arranging for concerted and harmonious action through a period extending to a distant future. Before a branch of industry has attained sufficient importance to claim international recognition, it has usually gone through the process of considerable development in different countries; and in each of these developments it has often received a stamp of local character which makes it difficult to reduce the whole to one uniform system. But in the case of electricity there were fortunately present special circumstances which facilitated the adoption of uniform standards. Foremost among these was the fact that the development of its practical applications, in other departments than telegraphy, were so recent that it was not too late to legislate for it as though it were but just about to begin. Secondly, the international character of telegraphy, and the fact that the manufacture of its apparatus had always been confined to the great centres of civilisation, had both tended to limit the number of existing systems of measurement, and prevented that multiplicity of standards which would certainly have arisen had such manufacture been carried on in numerous and in isolated localities. But by far the most important influencing circumstance was the happy idea due to the British Association of adopting standards based on absolute measures. The Association did not allow the idea to remain barren; but, through the instrumentality of its Committee on Electrical Standards, it gave to the world the admirable units of the Ohm, the Volt, and the now re-christened Weber; and the eminent men who formed that Committee may now point with honourable satisfaction to the fact that the Electrical Congress decided unanimously to recommend for universal acceptance those units which that Committee so early adopted.

With the single exception of the unit of current which, in order to avoid an ambiguity in the signification of Weber, receives the title of Ampère, the names are left substantially without change.

The adoption of these units for international use is to be preceded by a new and more careful redetermination of the ohm at the hands of the great physicists of all nations. And it is intended that this redetermination shall result in a standard for general adoption. Thus electricity will be the first of the practical sciences to be freed from all difficulties due to local standards; and it is to be hoped that this example may be followed in other sciences concerned with practical life.

The following are the actual resolutions adopted by the International Congress of Electricians at the sitting of September 22, 1881:—

1. For electrical measurements, the fundamental units, the centimetre (for length), the gramme (for mass), and the second (for time), are adopted.

2. The ohm and the volt (for practical measures of resistance and of electromotive force or potential) are to keep their existing definitions, 10^9 for the ohm, and 10^8 for the volt.

3. The ohm is to be represented by a column of mercury of a square millimetre section at the temperature of zero Centigrade.

4. An international commission is to be appointed to determine, for practical purposes, by fresh experiments, the length of a column of mercury of a square millimetre section which is to represent the ohm.

5. The current produced by a Volt through an Ohm is to be called an Ampère.

6. The quantity of electricity given by an Ampère in a second is to be called a Coulomb.

7. The capacity defined by the condition that a Coulomb charges it to the potential of a Volt is to be called a Farad.

The remainder of the work of the Congress consisted mainly of the discussion of various interesting questions bearing upon electricity; and although these did not in many cases issue in precise recommendations, yet they were not altogether devoid of practical results. The questions which chiefly attracted its attention were those of terrestrial magnetism and earth-currents, atmospheric electricity, and the more practical but perplexing question of lightning conductors. In all these matters the need of close and continuous intercourse between the observers of different nations was strongly felt; and the Congress passed resolutions recommending combined action both in the way of observations carried on simultaneously and with like apparatus, and also of frequent if not continuous telegraphic communication of the results of these observations. The organisation of so extensive and perhaps so costly a system of combined observations must depend to a great extent on the various Governments, and also on the goodwill and generosity of the great telegraphic companies; but it is much to be wished, for the sake of science, that some progress in that direction may soon be effected. The present state and prospects of electro-physiology also received careful discussion, but the difficulties of the subject precluded any definite conclusions. The same was the case with the question of photometry as applied to the intense light with which electricity furnishes us. Resolutions recommending the adoption of certain provisional photometric standards were passed; but these only evidenced the strong feeling that prevailed in the Congress, that some new departure must be made, and that a new standard of illumination (such as perhaps the glow of platinum on the point of fusion) must eventually be adopted for electric lights.

I have described the more important of the results of the

deliberations of the Congress. Perhaps, however, the most important of all (with the exception of the choice of electrical units) will prove to have been the impetus given to electrical science by the interchange of ideas that took place among the leading physicists of all nations, and the light that was thrown on the various problems which came under discussion in the meetings of the Congress.

I cannot conclude this imperfect sketch of this important Congress better than by quoting the eloquent words of M. Dumas at the conclusion of its sittings: "Greek mythology, in its happy personification of the forces of nature, placed the winds and the waves under the direction of divinities of the second rank; it made the celestial representative of light its god of poetry and of the arts; and by an admirable forethought, it reserved lightning for Jupiter. Science and industry have long since laid their hands on the forces which air and water have placed at the disposition of man. Steam, animated by fire, has enabled him to overcome many obstacles and to rule the waves. Light has no longer any secrets from science, and the arts are daily multiplying its marvellous applications. But there remained one labour to accomplish: namely, to wrest lightning itself from the hands of the ruler of the gods, and to bend it to the needs of humanity. This is the feat which the nineteenth century has now accomplished, and of which this Congress is the evidence and the witness. This feat will mark an epoch ever memorable in history; and, amid the turmoil of politics and of questions which agitate the human mind, it will be recognised as the characteristic feature of our era. The nineteenth century will be the century of electricity."

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following is the speech delivered in the Senate House on November 24 by the Public Orator (Mr. J. E. Sandys, Fellow and Tutor of St. John's) in presenting Dr. Thomas Sterry Hunt for the Honorary Degree of LL.D.:—

"Dignissime domine, domine Procancellarie, et tota Academia:

"Scientiam illam Geologicam, quae, in orbis terrarum origine et natura investiganda, neque temporis finibus terminatur neque saeculorum spatio coercetur, nos certe pro rei magnitudine, temporis praesertim angustiis impediti, orationis brevissimae intra spatium laudare non possumus. Iuvat potius hodie scientiae tam magnae professorem insignem vestro omnium nomine salutare, qui in republica illa maxima trans Atlanticum natus, nostrae tamen, provinciae Canadensis rupibus explorandis quinque et viginti annos dedicavit; qui de omnium animantium (ut nonnullis videtur) antiquissimo, quod Eozoon Canadense nuncupatur, doctissime disputavit; qui (ne plura commemorem) non modo vetustissimorum illorum saxorum, quae Laurentia nominantur, sed aliorum quoque complurium originem primam vicesque varias sagacissime investigavit. Quid autem si, in tot tantisque argumentis totiens retractandis, non semper sibi constare, non semper eadem sentire, visus est? Vos certe ex Academicae philosophiae disciplina didicistis, virum vere sapientem (ut Ciceronis nostri verbis utar) 'quod dixerit, interdum, si ita rectius sit, mutare; de sententia discedere aliquando.' Ceterum idem necessitudinis vinculo in perpetuum duraturo nobiscum idcirco coniunctus est, quod professoris illius nostri, qui has inter umbras plusquam quinquaginta annos studiis Geologicis lumen praetulit, et interpres et defensor egregius exstitit. O utinam hospiti nostro, nuper ex Italia ad nos advecto, mox autem, favente (uti par est) Neptuno suo, in patriam transituro, inter tot aedificia variis doctrinae studiis consecrata, novum illud Museum quod Nestoris illius nostri sempiternum fore monumentum iamdudum exspectamus, si non ad ipsum finem adductum, at inchoatum certe ostendere potuissemus. Ipsi meministis veteris poetae monitum illud:

"'Gratia ab officio quod mora tardat abest';

vestrum igitur officium est, viri Academici, qui beneficiorum tantorum non immemores estis, monumentum illud magnum ad exitum felicem quam maturissime perducere; nos interim nostro qualicunque laudis officio perfuncti, plausus illos vestros, qui hospiti nostro iam diu debentur, non iam amplius morabimur.

"Ergo vobis praesento Regiae Societatis Londinensis Socium, virum de studiis Geologicis optime meritum, Thomam Sterry Hunt."

OXFORD.—The Brackenbury Natural Science Scholarship at Balliol College has been awarded to Mr. T. F. McArthur, of Manchester Grammar School. *Proxime accessit*, Mr. J. J. Hart, Exhibitioner of the College. The following gentlemen distinguished themselves in the examination:—Mr. A. Ford Smith, Bedford Modern School; Mr. A. Wentworth Jones, Clifton College; and Mr. P. Hawkridge, Derby School. Mr. Ford Smith was elected to a Natural Science Exhibition.

The Statute respecting the inspection and licensing of lodging-houses was finally passed by Congregation on November 23. The following clauses were inserted concerning the duties of the Controller of Lodging-Houses and the Sanitary Inspector:—

"The Controller shall inspect every house proposed to be licensed for the residence of Undergraduates; he shall also visit, with or without notice, every licensed house once at least in each year, and report thereon to the Delegates.

"There shall be a Sanitary Officer appointed by the Delegates, for such period and under such conditions as they may determine. He shall inspect every house proposed to be licensed for the residence of Undergraduates, and shall make a Report to the Delegates on the sanitary condition of each house thus inspected. He shall also visit each licensed lodging-house once at least in every year, and any licensed lodging-house at any time by the order of the Delegates. The stipend of the Sanitary officer shall be determined by the Delegates in conjunction with the Curators of the University Chest.

"The Delegates may obtain, when occasion shall arise, additional advice, whether medical or of any other professsional kind. Any person whom they may thus employ shall receive such fee as shall be agreed on by the Delegates in conjunction with the Curators of the University Chest."

SOCIETIES AND ACADEMIES

LONDON

Meteorological Society, November 16.—Mr. G. J. Symons, F.R.S., president, in the chair.—Twenty-seven gentlemen were elected Fellows of the Society.—The evening was devoted to an account of the gale which passed across the British Isles, October 13-14, 1881, which had been prepared by Mr. G. J. Symons, F.R.S., with the assistance and co operation of Mr. C. Harding and other gentlemen. There is evidence of the storm being formed in the Atlantic, about 150 miles south of Nova Scotia on October 10, and that at noon on the 13th there was a considerable disturbance about 600 miles west of Galway. At that time there were scarcely any instrumental indications in the British Isles of the coming storm; the barometer was falling at Valentia, but not rapidly, and at some of the western English stations it was rising. The curves of barometric fluctuation show very plainly the advance of the depression from west to east, for while at Valentia the minimum occurred at 2 a.m. on the 14th, on the east coast of Norfolk it is recorded that it did not occur till 4 p.m. This fact, coupled with others, seems to indicate an easterly progression of the barometric minimum at nearly forty miles per hour. As far as the sea is concerned, the chief force of the gale was felt on the afternoon of the 14th in the German Ocean, and there the great loss of life and destruction to shipping seems mainly due to the exceptionally violent squalls which were peculiar to this gale, as well as to the extremely sudden manner in which the wind increased to hurricane force. The afternoon became quite darkened by the salt water blown into the air, so that it was impossible to see a ship's length ahead. The barometric chart for 9 a.m. on the 14th showed that the pressure in the north of England was an inch lower than in the south, and nearly two inches lower than in the South of France. The area over which injury was produced was very large, and although not without precedent, it was happily rare. The record of 56 lbs. per square foot at the Royal Observatory, Greenwich, was the highest ever registered in that locality, and close by thirty-five trees were blown down in the park, and fifteen feet blown off the top of a spire which had been erected about forty years, the stone of which shows no sign of decay, and which had retained its position almost, if not wholly, by the gravitation of its mass. The general opinion seems to be that the structural damage over the greater part of the country was by no means unprecedented, and in the greater part of Ireland and the south-west of England was not even of an unusual character; but along the east coast and in the East Midlands the damage was excessive, and on the north-east coast unprecedented. In Scotland the destruction of trees was enormous.—Mr. J. Wallace Peggs, F.M.S., also read a paper on the structural damage caused by the gale as indicative of wind force, and remarked that since the

Tay Bridge disaster attention had once more been directed to the subject of wind pressure. He suggested that a conference of delegates from societies specially interested in the subject should be held, who should make experiments and carefully consider the whole question.

Entomological Society, November 2.—H. T. Stainton, F.R.S., president, in the chair.—Exhibitions: An aberration of *Urapteryx sambucaria*, L., Mr. C. O. Waterhouse.—A new species of *Antheræa* from the Gold Coast; and some microscopic preparations of the saws, &c., of various *Hymenoptera*, prepared by Mr. P. Cameron of Glasgow, Mr. W. F. Kirby.—Pieces of honeycomb constructed on a bare wall, without any protection; and specimens and figures of new varieties of *Armadillium vulgare*, L., and *Porcellio scaber*, Latr., Rev. A. E. Eaton.—A specimen of *Lycæna icarus*, Rott., var *Icarinus*, Scriba, Dr. H. G. Lang.—An undescribed species of *Cicadidæ* from Borneo, with unusually developed opercula, Mr. W. L. Distant.—A female specimen of *Dufourea minuta*, Lep., Mr. T. R. Billups.—A specimen of *Scleroderma domestica*, Westw.; the larva was found parasitic on that of a Longicorn beetle in a pine-tree at Lyons; and some *Diptera* which attack figs in Turkey and Egypt, Sir S. S. Saunders (this led to an interesting discussion on fig-parasites and caprification).—Some remarkable tubes formed by Lepidopterous larvæ at Aden; and a specimen of *Cerura vinula*, L., which it was thought at first might belong to *C. erminea*, Esp., the President.—Papers read: Descriptions of new genera and species of Heterocerous *Lepidoptera* from Japan (concluded), by Mr. A. G. Butler; and a memoir on the various Dipterous insects (*Muscidæ* and *Tipulidæ*) destructive to cereals in Britain, by Prof. Westwood.

Geological Society, November 2.—R. Etheridge, F.R.S., president, in the chair.—Richard Paley Gardner, Henry Neville Hutchinson, Henry Johnson, William Regester, and George Tate, Ph.D., were elected Fellows of the Society.—The following communications were read: On the genus *Stoliczkaria*, Dunc., and its distinctness from *Parkeria*, Carp. and Brady, by Prof. P. Martin Duncan, M.B. Lond., F.R.S., F.G.S., Pres.R.M.S.—On the elasticity- and strength-constants of Japanese rocks, by Thomas Gray, B.Sc., F.R.S.E., and John Milne, F.G.S.—The glacial deposits of West Cumberland, by J. D. Kendall, C.E., F.G.S.

EDINBURGH

Royal Society, November 28.—The following were elected office-bearers, viz.:—President, the Right Hon. Lord Moncreiff; Vice-presidents: David Milne Home, LL.D., Sir C. Wyville Thomson, LL.D., Prof. Douglas Maclagan, M.D., Prof. H. C. Fleeming Jenkin, F.R.S., Rev. W. Lindsay Alexander, D.D., J. H. Balfour, M.D., F.R.S.; General Secretary, Prof. Tait; Secretaries to ordinary meetings: Prof. Turner, Prof. Crum Brown; Treasurer, Adam Gillies Smith, C.A.; Curator of Library and Museum, Alexander Buchan, M.A.; Members of Council: Prof. Campbell Fraser, Prof. Geikie, Rev. Dr. Cazenove, David Stevenson, Prof. Chrystal, Sheriff Forbes Irvine, Prof. A. Dickson, the Right Rev. Bishop Cotterill, Rev. Prof. Duns, Dr. Ramsay Traquair, John Murray, William Ferguson.

PARIS

Academy of Sciences, November 21.—M. Wurtz in the chair.—The following papers were read: On the condition of achromatism in phenomena of interference, by M. Cornu. In a system of fringes of interferences produced with heterogenous light having a continuous spectrum there is always an achromatic fringe which plays the *rôle* of central fringe, and is found at that point of the field where the most intense radiations present a maximum or minimum difference of phase. M. Cornu indicates the properties of the achromatic line, and shows the inaccuracy of the accepted theory for determination of the central fringe.—Reactions of salts of gallium, by M. Lecoq de Boisbaudran.—On a bed of reindeer remains near Paris, by M. Gaudry. This bed was found by M. Vasseur at Montreuil, and the remains have been sent to the Museum. They comprise, with numerous bones of reindeer, remains of elephant, rhinoceros, horse, bison, freshwater shells, &c. The deposit (which is surmounted by beds of grey sand and mud) is supposed to belong to the great glacial epoch of boulder-clay. M. Gaudry is enabled to sketch the history of quaternary times in the Parisian basin.—Observations on the *rôle* of faults in the geological structure of the Western Alps, by M. Lory. Some large fractures can be traced continuously right through Dauphiné, Savoy, and Valais, producing longitudinal zones with different orographic characters and strata.—On the crystallisation of sulphides of cadmium and zinc, by M. Hautefeuille.—On the agreement of the curve of solar spots with the actions resulting from the eccentric motion of large planets, by M. Duponchel. Reviewing the observations collected by Wolf from 1608 to our time, he finds the mean period of the oscillations not 11·2 years, but 11·86, the time of a revolution of Jupiter, with which it seems really connected. The perturbations of the curve are distinctly *en rapport* with the times of revolution of the three large superior planets.—On the winter egg of phylloxera, by M. de Lafitte.—Elements of the orbit and ephemerides of the planet (217) Endore, by M. Callandreau. On some series for the development of functions with a single variable, by M. Halphen.—On a particular curve of the third order and on certain uniform functions of two independent variables, by M. Picard.—New method of dividing the circle into equal parts, by M. Pellet.—Integration of differential equations of the vibratory motion of a spherical bell, by M. Mathieu.—Numerical application of the theory of maximum yield of two dynamo-electric machines employed for transport of force, by M. Lévy. Referring to a case discussed by M. Deprez, he shows that, by adopting different resistances, he would obtain 10 horse-power at 50 km., with a maximum electromotive force of 5356 volts, instead of about 7000.—On M. Lippmann's method for determination of the ohm, by M. Brillouin.—Remarks on the electrolysis of water, by M. Tommasi. In decomposing water with a single element, copper wire being used as positive electrode, and platinum wire as negative, the quantity of copper dissolved is greater than the quantity deposited on the negative electrode; and this is explained by the thermal theory.—On the dif rmine of glycerine, by M. Van Romburgh.—On some spectral reactions of alkaloids and glucosides, by M. Hock.—Electric current produced by light, by M. Laur. Light affects the American process of amalgamation in Mexico. The author elucidated the action by experiments which reproduce, in complex form, effects that have been indicated by M. Edm. Becquerel (as that physicist pointed out).—On some new cases of phosphorescence in plants, by M. Crié. He lately observed *Auricularia phosphorea* and *Polyporus citrinus* to emit luminous radiations; also *Rhizomorpha* or the vegetative apparatus of many champignons; also *Xylaria polymorpha*. This is the first time emission of light has been observed in Ascomycetes.—Influence of the nature of food on sexuality, by M. Yung. He fed separate sets of tadpoles with fish, meat, coagulated albumen of hens' eggs, yellow of eggs, and with a mixed diet. These aliments do not appear to have a very distinct influence on the sex; but along with M. Born's experiments, those of M. Yung support the idea that a special diet afforded to young tadpoles from the time of leaving the egg, favours the development of a female genital gland.—Development of the egg of Melicerta, by M. Joliet.—On spermatogenesis in Selachians, by M. Hermann.—M. Hément communicated some further observations on the articulation of deaf mutes.—M. Daubrée presented an Italian work by Prof. Cossa, "Chemical and Mineralogical Researches on the Rocks and Minerals of Italy."

SMOKE-ABATEMENT EXHIBITION

ON the 30th ult. an exhibition was opened at South Kensington of appliances intended to prevent excessive production of smoke in household grates and in the furnaces and boilers of manufactories, and thus to remove from the fogs of great cities, and especially of London, one of their most offensive constituents, and that which is most potent in darkening the cities over which they spread themselves. The Exhibition is described as "international"; that title is, however, often given on rather a slender basis; and from what we can at present see, the main exhibits are British, although a few interesting objects are sent from Germany, Canada, and France.

The origin of the Committee, which has for the last eight months systematically endeavoured to direct the minds of Londoners to the question of bringing into practical use some means of lessening the smokiness of London, if not rendering London smokeless, is described in the official Report as follows; and as it may be hoped that this Exhibition is only the beginning of a movement of which, with the aid of perseverance, energy, and scientific ingenuity, much may be expected, it is interesting to place the history of the movement upon record.

"The subject of the abatement of smoke, with the view of purifying the atmosphere of London and lessening the deleterious character of London fogs, has been vigorously taken up by the National Health Society during the past year. In the spring of 1880 the subject was brought under the notice of the Committee by Mr. Ernest Hart, the Chairman of Council, as one which he was desirous of taking up actively, with the co-operation of the Committee, and he was requested to take steps to bring the question into a practical form for further proceeding. With this view Mr. Hart placed himself in communication with Prof. Chandler Roberts, F.R.S., Professor of Metallurgy at the School of Mines and Chemist to the Mint, who undertook to make an examination of existing methods of combustion of coal in household grates and in furnaces. Further steps were taken to obtain details of the existing apparatus in use in different parts of the kingdom, and a considerable collection of documents was made, which have been placed at the disposal of the Committee subsequently formed. In July Mr. Hart learned from Miss Octavia Hill, the Treasurer of the Kyrle Society, that that Society was contemplating some action in the like direction, and it was arranged between Miss Hill and Mr. Hart, that with the approval of the respective societies a joint committee should be formed, with the object of continuing the movement. Such a committee was accordingly nominated, and met at the National Health Society's rooms; a definite course of proceeding was resolved on, and a programme was sketched out. Various eminent persons known to be specially informed on the subject (not all connected with either Society) were asked to join the Committee."

Among those who have given most active assistance are Dr. Siemens, Capt. Douglas Galton, Mr. Atchison, and Col. Festing, R.E.; but it is needless to say that all the eminent persons in art, literature, and science who have been asked to join have willingly given the valuable aid of their names, so that the Committee is a very representative one. The Exhibition includes a great variety of exhibits divided into the following sections:—

In *Section A.* will be found: Open coal-fire grates, stoves of all kinds, kitcheners, kitchen ranges, draught-regulators, base burners, and other appliances devised to prevent the liberation of smoke from bituminous coals or to consume anthracite and other smokeless fuel.

Section B.—Gas fires, open grates and stoves, gas producers, and gas-heating apparatus of all kinds for domestic use.

Section C.—Appliances for heating rooms and buildings by hot air, hot water, and steam circulation.

Section D.—Gas engines, boiler furnaces, fire-bars, mechanical stokers, smoke-preventing furnace bridges, and other appliances for steam-engines and for general industrial purposes.

Section E.—Anthracite and other smokeless coals, bituminous and semi-bituminous coals, patent and other fuels.

Section F.—All foreign exhibits. Improvements in chimney flues, ventilating apparatus, and novel inventions for regulating temperature, &c.

Buildings have been fitted up for the purpose of testing the efficiency of grates, stoves, and other appliances suited for domestic use; and trials of various fuels and boiler appliances will also be conducted in the Exhibition Buildings, and at certain factories where facilities have been offered by the proprietors.

The Committee have secured the services of Mr. D. Kinnear Clark, M. Inst. C.E., to superintend the trials under the direction of the Executive Committee. In conjunction with Dr. Frankland, F.R.S., Prof. W. Chandler Roberts, F.R.S., has undertaken to make certain chemical tests in connection with the trials of fuel grates and stoves.

It is not unreasonable to expect that such an exhibition carried out under the direction of a Committee of Experts, which includes Prof. Abel, C.B., Royal Arsenal, Woolwich, A. T. Atchison, M.A., William R. E. Coles (Hon. Secretary), Col. E. R. Festing, R.E. (Science and Art Department, South Kensington), Capt. Douglas Galton, C.B., F.R.S., Prof. Edward Frankland, LL.D., F.R.S. (School of Mines, South Kensington), Sir Ughtred Kay-Shuttleworth, Bart., Dr. Siemens, F.R.S., LL.D., J. Lowry Whittle, Temple, will be of national value. It will tend directly to a better utilisation of coal and coal products, by determining practically and scientifically the means which are actually available for heating houses as at present (and as may be) constructed without producing smoke, as the Committee will be enabled to examine the subject generally and to report for public information upon the relative adaptability of the various coals and appliances to the requirements of every class of the community. Trustworthy information will be obtained upon which to base sufficient and equitable amendments of the existing laws regarding smoke; and the Committee will also ascertain and make known the comparative value of existing appliances for the utilisation of gas for the purpose of heating.

It must be admitted that for years past the air of London has steadily deteriorated, and that in London, which 150 years ago was famous for its roses, it is now impossible to get a rose to blossom or conifers to grow. Homely but practical evidence of the actinic influence of light, which is so essential to the health of plants

and animals, was given by Mr. Ernest Hart at one of the many meetings which have been held on the subject, when he mentioned that wax manufacture had been, during the last twenty years, successively driven further and further from the centre of London. Ten years ago it was possible to bleach wax in the sunlight at Shepherd's Bush, but the factory was now removed to near Richmond, as it was found that the bleaching power of the sun for the greater part of the year was almost nullified by the pall of smoke which hangs over the metropolis. We shall not speak to-day of the various appliances of which we have as yet had but a hasty view, but it is only fair to say that there are shown at the Exhibition a number of grates, some of which, such as the new "Everitt" grate shown by Messrs. Barnard, Bishop, and Barnard; Mr. Crane's grate, shown by Deane and Co.; and in some respects the "Excelsior" grate of Mr. Archibald Smith, mark distinct advance. The possibility of consuming the smoke of bituminous coal in ordinary grates by forcing the draught of air and smoke downward through the fire before it is allowed to escape has been shown, as has also the facility with which hard anthracite smokeless coal will burn in open grates without any sort of blower or other such contrivance. In addition to these there is an extremely interesting series of exhibits of mechanical stokers, fire-bars for furnaces, a new gas-kiln which will be shown in operation, as well as Dr. Siemens' gas-regenerator. Some extremely good household stoves and fire-places are sent from Germany and Canada.

DOUBLE-STARS

Observations of Double-Stars made at the United States Naval Observatory. By Asaph Hall, Professor of Mathematics, United States Navy, and Rear-Admiral Rodgers, U.S.N., Superintendent. (Washington: Government Printing Office, 1881.)

WE welcome another addition to our knowledge of the positions and distances of double stars. Prof. Asaph Hall has published a volume containing 1614 observations of such stars made by him chiefly with the 26-inch refractor at the Naval Observatory at Washington. The objects of the observations are two. Firstly, the detection of constant errors of observations by the measurements of double-stars from a selected list, and comparing such measures with those of other observers made as nearly as possible simultaneously; and, secondly, the measurements of double-stars generally.

The list of stars adopted is that prepared by Otto Struve, with a few additions of stars of greater distance. There are 30 stars in all, and 296 complete sets of measures of these have been made, each set consisting of four measures of position and two double measures of distance, except in cases where the stars exceed 3″ in distance, when four were taken. The measures appear to be made with care, and the discrepancies are not greater than may be expected from night to night.

In connection with this subject Prof. Hall has applied a geometrical test to such observations by means of measures of the multiple stars Σ 2703 and Σ 311 and the stars in the trapezium of Orion. He says:—

"In the case of three stars A, B, C, if we take the origin of co-ordinates at A, and observe the angles of position and the distances of B and C only, then these quantities are independent, and we may put their differentials equal to zero. But if we observe also the angle of position and the distance between B and C we have obtained more quantities than the geometrical conditions require, and must adjust the parts of the triangle by the method of least squares."

In the case of the triangles and the quadrilateral there appear to be no important systematic errors.

Prof. Hall gives a detailed account of the use of "rough circles" for setting the instrument on a star. These circles are the edges of the ordinary setting circles divided by lines of black paint on a white ground so as to be read without trouble, a method already adopted in some observatories in this country. He also describes the difficulties he has had with the driving clock, difficulties which are too often experienced with driving clocks of all kinds, and often arising from insufficiency of power and strength of parts to stand varying strains, and often dust and damp, which ordinary clocks do not generally experience. The dome, which is 42 feet in diameter, now turns with more difficulty, and if our experience is worth anything, such a difficulty once commenced will keep on fast increasing, and will very materially militate against the continued use of the instrument beneath it. The flexure of the telescope, which is 31 feet in length, and of the mounting, is small, and the working of the instrument very satisfactory.

A filar micrometer has been used for all the observations, and great care has been taken to test its accuracy, which is all that can be desired; but we note that the wires are illuminated by a lamp held by an assistant, a method somewhat primitive, as Prof. Hall says, and a waste of energy which might, we should have thought, have been useful elsewhere.

In all the ordinary observations four measures of position and two double measures of distances have been taken, and in all cases the head of the observer was kept in an upright or natural position. Owing to this we shall expect to find, on comparison of the list of test stars with others, a considerable error depending on the position of the stars with the horizon. No doubt practice has a great deal to do with it, but we have generally understood that the observations were more accurate and differed less *inter se* when made with line joining the eyes parallel to that joining the stars under observation.

Prof. Hall has included a good many very close stars, and it is to them that the large telescope can be most profitably turned, leaving the wider ones for the small instruments, with which they are well able to deal.

OUR BOOK SHELF

Zoological Atlas (including Comparative Anatomy), with Practical Directions and Explanatory Text for the Use of Students. Invertebrata. By D. M'Alpine. 249 Coloured Figures and Diagrams. (Edinburgh and London: W. and A. K. Johnston, 1881.)

THIS Atlas is prefaced by the following remarks:—"In treating of the Invertebrata I have thought it advisable to depart slightly from the plan followed with the Vertebrata. There are five great divisions of Vertebrates recognised by naturalists, and a type or so of each was found to answer the purpose in view; but among Invertebrates the range of structure is immensely greater, and

the typical forms are thereby necessarily increased. In order to preserve the just proportions of the subject, and out of the whole make a fair selection, I have treated most of the forms in less detail than the Vertebrates." With the above statement no objection could be found; as to the method of carrying it out, we notice that while four out of the sixteen plates are devoted to illustrations of the group of Protozoa, there is not even a single figure given of the Sponges, nor of the Hydrozoa, nor of the Actinozoa, and for their absence we can find no other excuse than what is given in the above quotation. As to the plates of Protozoa, we perceive that there is no exact indication of the size of the forms figured, unless indeed in a footnote, which states that the forms figured "are all *microscopic*, with the exception of the Nummulites." Now if there is one thing more than another that a student requires to be reminded of while studying "microscopic" forms, it is that they vary immensely among themselves as to size, and it is surely necessary that he should have some definite ideas as to those sizes beyond the range of unassisted vision, such as he may be presumed to have of those objects within this range. Neither has the author been to our mind happy in his selection of forms of the Protozoa "from standard works on the subject." His Atlas is meant for students in this country, and where are they to get specimens to work with of such genera as Protogenes, Vampyrella, Myxastrum, Protomonas, Protomyxa, Lieberkühnia, and the like. The student interested in "pond-life" may possibly admire the exquisite and artistic delineations of their old favourites, *Paramœcium*, *Daphnia*, *Cyclops*, &c., given in the Atlas. The festooned surface of *Paramœcium*, the appendages of *Daphnia* and *Cyclops* are certainly figured as they have never been heretofore. It is really refreshing to turn from the old and well-worn figures to the bold originality of these plates; in them the author has courageously followed the theory of zoological representation laid down by the celebrated German artist with reference to *Camelus*, sp., but is scarcely to be congratulated on the wonderful results he has achieved. Some of the diagrams are acknowledged as from the originals of Huxley and Gegenbaur; these are good.

The Student's Handbook of Chemistry. With Tables and Chemical Calculations. By H. Leicester Greville, F.I.C., F.C.S. (Edinburgh: E. and S. Livingstone, 1881.)

"In the presence of so many good manuals on chemistry, the appearance of another may seem unnecessary," says the author in his preface. For "may seem" read "is," and the sentence expresses a truism. The author's book can, however, scarcely be classed amongst "good manuals." The statements of individual chemical facts are on the whole correct; the general arrangement of the book is clear; yet, considered as a manual of chemistry, the work must be pronounced a failure.

Attempts are made to explain the expressions "atomic weight," "molecular weight," "valency," &c., but without success. Atoms are confused with molecules; the ordinary definitions of these terms are certainly stated, but definitions taken by themselves are, as Hunter said, "Of all things on the face of this earth the most cursed."

Avogadro's law is stated on p. 26, but the conclusion deduced therefrom, viz. "the densities of all the elementary bodies in the gaseous condition are the same as their respective atomic weights, or, the atoms of all the elements in the gaseous state occupy the same space," is untrue, and does not follow from the generalisation of Avogadro.

The Daltonian atomic theory is stated much in the terms which might have been employed before the molecular theory of matter had been propounded. Such statements as that on p. 15, that oxides are called monoxides, dioxides, &c., according "as the compounds contain one, two, three, &c., atoms of oxygen respectively"; or that on p. 13, "that acids are spoken of as monobasic, &c., according as they contain one, two, &c., atoms of hydrogen replaceable by a base," show that the author has failed to grasp the teachings of the molecular theory.

The term "valency," we are told on p. 159, is used to express "the comparative saturating power of the different elements, taking hydrogen as the unit." Such a loose statement as this naturally prepares the way for the full acceptance of the "bond" view of valency, with all its inconsistencies and apparent, but unreal, explanations of facts; so that one need not be surprised to find (p. 160) the expression, hard to be understood by the uninitiated, "the affinity of these bonds."

A sentence on p. 161 may be quoted as a type of the kind of writing to be found in the works of those who are bound by the trammels of this pernicious system. "The disappearance of the active atomicity by twos, which is found to be always the case, has led Dr. Frankland to suggest that the bonds of union so disappearing are engaged in satisfying each other."

That part of the chapter on "The Higher Principles of Chemical Philosophy" which deals with compound radicles is equally unsatisfactory. Sulphuric acid may be assumed to contain the radicle SO_2. "The group SO_2 may be traced all through the compounds of sulphuric acid, thus: $SO_2(OK)_2$ $SO_2(ONa)_2$ SO_2CuO_2." Such a statement is harmful, and only harmful, to the student; in what light other than as an amusing plaything can he regard this conception of compound radicle? Why should he not trace the group SO_3, or the group SO, or the group SO_4 "all through the compounds of sulphuric acid"? Give him pen and paper, and if he have a little fancy he will trace you a most varied and pleasing number of groups "all through" as many compounds as you please.

The tabulation of facts concerning groups of elements and compounds is a good feature in this book, and likely to prove very useful to the student. The chapters dealing with organic chemistry are clear and succinct: had the author contented himself with recording leading facts, and left the "principles of chemical philosophy" alone, he would have produced a book of some merit, although not of merit sufficient to warrant him in adding another "Manual of Chemistry" to the list which is already so much too long.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The "Eira" Arctic Expedition

Those who advocate the despatch of a Government vessel in search of Mr. B. Leigh Smith's expedition betray only a partial acquaintance with the circumstances of the case. His having failed to return this season is no evidence whatsoever of his having met with disaster; for previous to his departure from England, certain people well understood that he was prepared to spend the present winter far north if he found it worth while to do so. It was this which prevented me from going with him (natural history work on hand precluding my absence from London for upwards of a year); for as I had collected plants and animals with him on a former expedition in Spitzbergen, he invited me to accompany him on his present trip to Franz-Josef Land. The *Eira* was well-provisioned for upwards of eighteen months, and in summer time fresh meat in abundance can be secured, which, hung up in the rigging, will keep good for almost an indefinitely long period. Thus the expedition has provisions enough for at least another year and a half from the present time, and there would be no need for them to starve two years hence. It is therefore rather

early to begin to feel uneasy about their safety on account of provisions.

The detention of the *Eira* in the north is more probably due to her being "beset" than to her having been "nipped" or run aground. Unless she has foundered before stores could be got out of her (when nothing could be done by any search-expedition towards enabling the crew to survive the winter), Mr. Smith and his men are doubtless having a fine time of it up there, in one sense of the words. If it came to the worst they would not be obliged to abandon the ship simply on account of her being hopelessly "beset," until the spring of 1883, because they could afford to wait for the chance of her being liberated next summer or autumn. Then, if she were clearly inextricable, they would do what is done by the crews of whalers under similar circumstances—haul boats or sledges, laden with provisions, over the ice to some place where, in the ordinary course of events, they could not fail to fall in with walrus-hunters, or from whence they might take a departure in their own boats to the most convenient country. Mr. Smith, to my personal knowledge, always counted upon being able to effect a safe retreat by these means, without unusual difficulty, if he should lose his ship: the despatch of an expedition from England in search of him never entered into his calculations. This will amply account for his not naming a *rendezvous*. In the Arctic regions it is best not to be tied down beforehand to any one *route* where there is a choice of several, lest if emergency arise it prove to be *pro tem.* precisely the most difficult of all.

In view of the above facts it appears premature to demand the equipment of a vessel to rescue the *Eira* as a matter of immediate urgency, although, if nothing be heard of her by this time next year, an expedition during the season of 1883 might be a reasonable precaution by no means uncalled for. If people want a ship to be sent out next year, why should not the agitation be an honest one for an Arctic expedition pure and simple?

Thorncombe Vicarage, Chard, Dec. 3 A. E. EATON

Helophyton Williamsonis

AT the late York meeting of the British Association two of my indefatigable auxiliaries in the work of Carboniferous investigation, Mr. Wm. Cash, F.G.S., of Halifax, and Mr. Thomas Hick, M.A., B.Sc., of Harrogate, described, under the name of *Hymenophylloides Williamsonis*, a new stem of a plant, which they had obtained from the Halifax beds. This plant is an extremely interesting one, since its cortical layer exhibits the large, open, longitudinal lacunæ, formed by dissociation, so common amongst aquatic plants. It is still more interesting since the septa separating the large lacunæ are rotate, each one consisting of a single layer of cells, and the whole combining to constitute a network with vertically elongated meshes. This arrangement approaches too closely to that seen in the living Marsileaceæ, to be overlooked in considering the possible affinities which it may indicate. The structure of the central vascular bundle as well as of its component vessels differs decidedly from that of the recent Marsileæ and their allies. But it differs still more widely from Myriophyllum, with which the generic name given to it by my two friends associates it. This circumstance alone makes it important to change the name. As yet we have found no trace of an angiospermous phanerogam in the Carboniferous beds, and any name suggesting the probability of the existence of such is apt to be misleading. But apart from this suggestion of improbable affinities a second reason exists for changing the name. Unger has already adopted that of Myriophyllites for a genus of Tertiary plants, and the two names approach too nearly to make it desirable that both should be retained. One point appears to be indisputable:—The structure of the bark already referred to indicates either a marsh or an aquatic plant—an interesting fact, since it is the first example of such a plant from the palæozoic rocks that has hitherto come under my notice. We have numerous so-called aquatic roots described by various authors—and possibly they may be what they are affirmed to be, though we have no proof that such is the case; but I think that no such doubts can exist in reference to our new plant. Under these circumstances I propose for this plant the generic name of *Helophyton*, a name which involves no foregone conclusions as to its botanical affinities. Detailed figures of it will appear in the next (12th) part of my memoirs "On the Organisation of the Plants of the Coal-measures.

WM. C. WILLIAMSON

Victoria University, Manchester, December 3

The Pronunciation of Deaf-mutes who have been Taught to Articulate

MY attention has just been drawn to the remarkable statement of M. Hément (*C. R.*, xciii. p. 754), that deaf-mutes who have been taught to articulate speak with the accent of their native district; and to the equally remarkable letter of Mr. Wm. E. A. Axon, published in NATURE (vol. xxv. p. 101), in support of the same proposition.

I may say in this connection that I have during the past few years examined the pronunciation of at least 400 deaf mutes who have been taught to speak, without remarking any such tendency as that referred to above. It is true that in a few cases dialectic pronunciations are heard, but it always turns out upon investigation that such children could talk *before they became deaf*. The peculiarity is undoubtedly due to unconscious recollection of former speech, and cannot correctly be attributed to heredity.

M. Emile Blanchard (*C. R.*, xciii. p. 755) has directed attention to the harsh and disagreeable character of the utterance of many deaf-mutes who have been taught to articulate, but it has been found in America that this can be overcome by suitable instruction. I am happy to be able to say that I have heard from congenitally deaf children perfectly distinct and agreeable articulation.

The mouths of deaf children are in no way different from our own.[1] Deaf mutes do not naturally speak the language of their country for the same reason that we do not talk Chinese—*they have never heard the language*. They are dumb simply because they are deaf; and I see no reason to doubt that all deaf-mutes may be taught to use their vocal organs so as to speak at least *intelligibly*, if not as perfectly as those who hear.

In most, if not in all, of our American Institutions for the deaf and dumb, articulation is now taught as a special branch of education; and in many of our schools all instruction is given by word of mouth, as it has been found that large numbers of deaf children can be taught to understand spoken words by watching the movements of the speaker's mouth.

So successful has articulation-teaching proved in America and in Europe, that dumbness will soon be universally recognised as a mark of neglected education.

ALEXANDER GRAHAM BELL, Ph.D.
(Nat. Col. for Deaf Mutes, Washington)

London, December 5

The Function of the Ears, or the Perception of Direction

I SEE the above to-day in NATURE (vol. xxiv. p. 499) as a matter brought before the British Association at York, and as I can forward some results of experience, I beg to send the following:—In the cold season of 1868 I had to cut a straight line through dense forest half a mile long, between two given mounds, and availed myself of the known capability of Asamese in telling direction in such cases. Placing a man on one mound to shout now and then, a party of us went to the other mound and listened. On hearing the shouts I placed a long thin bamboo on the ground pointing from a peg in the direction of the shouts. While the men were clearing a space around I put another small peg in the ground, marking where the point of the bamboo fell. I took the bamboo up, and made the head man relay it himself, which he soon did, almost exactly where I had pegged it; thence we cut a true straight line, setting up peeled rods at every 50 yards, and eventually came out at 24 feet from the mound, in a distance of 45 chains. The jungle was dense, and we could never see more than about 12 or 14 yards in front. Lately having moved to a place where there are five tea-gardens in a semicircle around me, at distances of 5, 6, 4, 4½, and 4½ miles distant, I have heard several gongs in the early morning, and taking the bearing of the most audible, plotted it on the Government map, when it came out exactly among the houses in the "station" of the one at 4 miles; a repetition on other mornings confirms the direction. Distance does not seem any drawback, provided the sounds are loud enough; for in the great

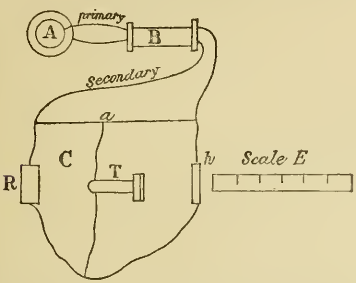
[1] I have examined the vocal organs of several hundred deaf-mutes, and while I have observed the most extraordinary differences in the size and shape of the palate, and in the appearance of the tongue, I have observed the same peculiarities in the mouths of hearing children, who talk perfectly well. The proportion of malformation of the vocal organs among deaf-mutes is certainly not greater than among hearing children. We occasionally meet with cases of cleft-palate, of double rows of teeth, and of tongue-tie, but such cases are altogether exceptional, and the vast majority of deaf-mutes have vocal organs as perfect as our own.

earthquake of January, 1869, the direction of the loud banging sounds like artillery was carefully marked against a peak in the Naga Hill range. Bearings by the prismatic compass subsequently sent to Calcutta to Dr. H. B. Medlicott, turned out to be within 3° of the true line to Cheduba and Ramree, the active volcanic centre, 550 miles off. I cannot exactly see how the difference of the *intensity* assists us in directing to the sound. I find I judge that best by facing it and remaining still, and verify the direction best by *looking* (with the eyes only) about 10° to right, and then 10° to left, which, if I do not move the head, soon enables me to fix by eye the direction pretty close.

Sibsagar, Asam, October 27 S. E. PEAL

An Audible Photometer

IN your issue of September 22 (vol. xxiv. p. 491, British Association Reports) Mr. Lant Carpenter mentions an idea of his about an "audible photometer." The same idea occurred to me some six months ago. As my plan seems to be much more simple than Mr. Carpenter's, dispensing with intermitting beams and rotating disks, perhaps you will allow me a little space to describe it. I require only one photophonic receiver, whereas Mr. Carpenter mentions "two precisely similar receivers," which is difficult, if not wholly impossible, to obtain. A is a small battery, B an induction-coil with the ordinary vibrating magnetic interrupter, and with a high-resistance secondary coil; C is the Wheatstone-bridge combination, S E a selenium cell, with its working surface



turned to the scale E; R is a high resistance of about the value of the selenium cell; a is a sliding contact, T a high resistance telephone. Now I place on the scale E a standard candle at a distance d from selenium cell, and move the sliding contact till no sound is emitted from the telephone. Then the wire connections are left wholly unaltered, and the candle is taken away. Now I place the light I wish to compare with the standard candle on the scale E, and move it along the scale till the telephone is again silent. Be the distance of the light from the selenium cell now D, then its luminous intensity is

$$\frac{D^2}{d^2} \text{ standard candles.}$$

As, on after-thought, I greatly doubted the fitness of selenium for photometric purposes (which doubts became the stronger the more I read about the subject), I did not pursue my idea, which could only result in an addition to the long list of practically useless photometers. The above may perhaps be used as a college experiment for demonstrating the law of the square of distances. J. W. GILTAY

Delft, November 21

Extraordinary Atmospheric Phenomenon

I INCLOSE a paragraph from the Glasgow *Evening Citizen* of this date relating to that peculiar form of lightning known as fire-balls. The explanation of the explosion in the funnel is, I think, erroneous, it having been caused by the explosion of the fire-ball, thus driving out the smoke by the fire-doors. The aurora was very bright here on Wednesday evening, showing Piazzi Smyth's line with a small direct vision spectroscope. Before the eye became sufficiently sensitive for measurement, clouds cut off the bright part. The aurora was a general bright northern glow without streamers, and was observed brightest a little after eight (p.m.). These notes may be of use to you in connection with those of other observers. Extraordinary Phenomenon of the Storm

Those on board the Campbelton Steamer *Kinloch* (Capt. Kerr), which left Greenock on its usual run about half-past eleven o'clock on Tuesday morning after the storm that raged during the night, had a somewhat extraordinary experience while passing down the Firth. The vessel was enveloped in a dense shower of hail, and for some time it was awfully dark, and occasionally the vessel was lit up by vivid flashes of lightning. One of the flashes was very bright, and its shape was something like that of the arteries of the human body, with a central column all shattered and broken. About noon, while opposite the Cloch Lighthouse, and not far from the shore, the captain observed immediately over the ship what appeared to be a series of clear balls of lightning, each about a foot in length, and resembling a chain, except that they were disconnected. This phenomenon was quickly succeeded by an explosion in the funnel of the steamer, and several balls of fire upon the bridge running about, and then bounding off into the water. The first impression of the spectators was that something had exploded on board, but on inquiry it was found that this was not the case. The mate stated, however, that a ball of lightning had almost struck him where he stood. A fireman rushed upon deck to see what had happened, as the engine-room was filled with smoke, and a choking sensation was experienced below. The explanation appears to be that a portion of the lightning had passed down the funnel until its force was spent by the fire, and the sudden recovery of the draught of the funnel afterwards accounted for the loud report that was heard. The captain, in his long experience at sea, never encountered such a phenomenon before, and it may be taken as an indication of the extraordinary atmospheric forces which had been at work during the storm, and which seemed to centre in this locality.

Papin

IN the review of my "Life and Letters of Papin"[1] in NATURE, vol. xxiv. p. 378, the hope is expressed that I might succeed "to fill the *lacunæ* in the career of this remarkable man." The only important blank remaining now in our knowledge of Papin's life consists in our ignorance of the time of his death. We may rest assured that he died in London, and therefore this blank is not likely to be filled but by a person who is familiar with the city and its inhabitants of the present and of the beginning of last century. Papin died about 1712. During 1709 he lived at "Madam Postal chez M. Charron, apothécaire dans Compton Street, proche St. Anne." As it is not probable that he changed his lodgings before his death a search in the registers of the district to which Compton Street belonged (if they are in existence) would lead to results equally important for the history of science and for that of technology. Maybe a reader of this note who enjoys such opportunities will render me his assistance in this thankful task.

I avail myself of this opportunity of correcting a few slight mistakes which have found their way into the otherwise excellent *résumé*. Not Papin but Leibnitz is the author of the letter of February 4, 1707, which contained the first idea of the "hot-air engine." Leibnitz is therefore the inventor of the same. That boat, in which Papin left Cassel in 1707 to sail to Bremen, was not a "steam propeller boat," but a small ship with paddle-wheels to be worked by the sailors. It was not Papin's intention to proceed to England in that boat. He left Cassel with proofs of the favour and goodwill of the Landgraf, which remained unchanged to the end. Lastly, before Papin no steam-engine existed; he is the real inventor of the same, for he in 1690 first announced the idea, and tested it by experiments of utilising the pressure of steam as motive power for engines. This, his first engine, had a piston inside a cylinder. Such an arrangement was not at all new at that time; other machines had the same, as, for instance, the gunpowder engine of Huyghens, which suggested the invention of Papin. Leibnitz corresponded with the inventor about this engine much later, and made valuable propositions, but the correspondence of these

two *savants* did not commence before 1692. It is therefore out of the question to credit Leibnitz with the invention of the steam-engine or even with the application of the piston principle in the steam-engine.

Cassel

A Question for Naturalists

MR. PAUL DU CHAILLU, in his "Land of the Midnight Sun," tells us that "the time of dropping the horns in a herd (of reindeer) varies from March to May." This may be true as regards the young males up to two or three years of age, and of the does, but it is questionable as regards the full-grown males. If my memory serves me correctly, the full-grown bucks brought to this country with some Lapps a year or two ago, and exhibited at the Aquarium, shed their horns in December or January. The experience of a gentleman—one of the highest authorities in such matters—who holds a most important position at the Zoological Gardens, supports my view. Can the Lapps have two kinds of reindeer which shed their horns at different seasons? I know that the full-grown male reindeer of the barren grounds of America drop their horns in the latter part of November and in December (which does away with the erroneous idea that this animal used the broad brow antler as a shovel for clearing away the snow so as to reach his food); the young buck of two or three years retains his horns until spring, and the full-grown female does not shed her horns until May or June, usually after having dropped her calf.

Earthquake Vibrations

IN a note in your issue of August 25 on my account of the earthquake of March 8, 1881, felt in Japan, it is said "that from the phenomena of the shock and from experiments on artificial earthquake waves produced by letting an iron ball weighing about one ton fall from a height of about thirty-five feet, Mr. Milne agrees that the waves that are felt are transverse to the line of propagation of the shock." Lest it should be thought that all the earthquakes which shake the residents in Japan are composed of transverse vibrations, allow me to make the following brief statements:—

1. In the earthquake of March 8 my seismographs chiefly indicated east and west motions, whilst time observations made in Yokohama, as compared with similar observations made in Tokio, showed that the earthquake must have travelled up from the south. This particular earthquake, as recorded in Tokio, might therefore be called a transverse or diagonic shock.

2. In other shocks normal or direct vibrations are the most prominent. These shocks might be called euthutropic.

3. Others again are compounded of direct and transverse motions, and might therefore be called diastrophic. Thus my records of the shock of July 5, 1881, very clearly showed a variation in the direction of the motion of the ground. At the commencement of the shock the motion was N. 112° E.; $1\frac{1}{2}$ second after this the direction was N. 50° E.; $\frac{3}{4}$ second more it was N. 145° E.; and after a similar interval N. 62° E. These and other changes were very clearly indicated in the diagram written by a double-bracket seismograph.

4. Anaseismic shocks, or those where vertical motion is prominent, which vertical motion may sometimes be a component of the transverse motion, appear to be rare.

5. In the artificial earthquakes produced by the blow of a falling ball the seismographs very clearly wrote both normal and transverse vibrations. When bracket-ring seismographs were used, these two sets of vibrations could be separated and their respective velocities, &c., measured. When a single component seismograph was used, the resultant motion due to the composition of these two sets of vibrations was recorded. The results of these experiments, which experiments were made in conjunction with my colleague Mr. T. Gray, will very shortly be published.

The Geological Survey of Italy

MY friend Mr. W. Topley, in his interesting account of the Italian Geological Survey (NATURE, vol. xxv. p. 86), is quite right when he states that the geological surveyors seem now to have definitely fixed the position of the Carrara marbles in the Trias. If, however, he means to imply that the geological world at large will accept this decision, I fear he is mistaken. The patient toil, spread over many years, and carried on by M. Coquand with more than due regard to Buffon's advice to geologists, "*Il faut voir beaucoup et revoir souvent,*" gives him such authority when speaking on the structure of the Apuan Alps and the Campigliese, that nothing but the most absolute proof that he is wrong in regarding the metamorphic marbles of Carrara, as well as those of the Pyrenees (St. Béat, &c.), as being of Carboniferous age, will prevent foreign students of Italian geology from accepting his views on the matter. I have read, I think, all that has been written in Italy by De Stefani and others on the point in question since the publication in full of M. Coquand's mature conclusions in the *Bulletin de la Société géologique de France*, in 1874, and I still regard his position as entirely unassailed. In 1876 I published in the *Geological Magazine* a short *résumé* of M. Coquand's results, to which I would refer any who are interested in the subject.

G. A. LEBOUR

OUR ASTRONOMICAL COLUMN

THE PROVINCIAL OBSERVATORIES OF FRANCE.—We have before us the "Rapport adressé par le comité consultatif des observatoires astronomique de province, à M. le Ministre de l'Instruction Publique," signed by M. Lœwy, as reporter. In the year 1880 a great impulse appears to have been given to what is termed the reform of French astronomy, a considerable grant having been obtained by the Minister of Public Instruction, which allowed of most material improvement in the equipment of the several observatories of the provinces. Stress is laid upon the reorganisation of the observatory at Algiers, which is placed under the direction of M. Trepied, and the Committee urge that special attention should be given to the proper equipment of an establishment which has the advantage of so exceptional a climate. The observatory at Marseilles is still under the direction of M. Stephan, who has done such excellent work for many years past, and MM. Borrelly and Coggia were the assistant-astronomers in 1880: a revision of the star-catalogue formed by Rümker at Hamburg is in progress at Marseilles. At Toulouse, M. Baillaud is the director; he proposes to devote special attention to the observation of the variable stars. In 1880 a regular course of observations of the solar spots was maintained, and it is mentioned that during the nights August 9–13 three observers counted upwards of 1200 meteors of the Perseus shower. At the observatory of Bordeaux, M. Rayet is director; an equatorially-mounted refractor of 14-inches aperture has been ordered from Merz of Munich, and a second of 8-inches aperture is also to be provided. Two observers were engaged in 1880 upon a revision of the charts of Chacornac. The observatory at Lyons includes four stations, three of them devoted to meteorology: the astronomical station is at Saint-Genis-Laval, where M. André is director, and the principal instrument in process of construction in 1880 was a meridian-circle of 6-inches aperture by Eichens. The State-subvention to these observatories is 81,000 francs, and further funds are provided by the cities of Bordeaux, Marseilles, and Toulouse for their respective establishments.

The Report is a very encouraging one in its bearing on the advancement of practical astronomy in France.

DENNING'S COMET.—Dr. Hartwig has corrected his first ellipse with the aid of an observation by Prof. Winnecke on November 19, in addition to earlier ones at Marseilles and Strasburg, and now finds the period of revolution 8·8334 years, or 3226·4 days. With the corrected orbit the nearest approach to the orbit of Jupiter occurs in 222° 35′, heliocentric longitude, where the distance is 0·154, the comet is at this point about 593 days before perihelion passage. It approaches nearest to the orbit of Venus 5·6 days after perihelion passage in longitude 30° 45′, where the distance is only 0·0226, while in longitude 82° 35′, about 36·7 days after perihelion passage the comet's distance from the earth's orbit is at a minimum of 0·0346.

A NEW COMET.—A Dunecht circular issued on November 22 contained elements of a comet from observations made by Mr. Wendell at the observatory of Harvard College, U.S., on November 17, 19, and 20. Prof. Winnecke has observed this comet as follows:—

	Strasburg, M.T.				R A.				Decl. N.		
	h.	m.	s.		h.	m.	s.		°	′	″
Nov. 25	9	54	33	...	0	30	39·46	...	63	52	2
26	6	3	31	...	0	25	25·44	...	62	35	21

These places differ considerably from the ephemeris telegraphed to Dunecht.

THE PRESSURE ERRORS OF THE "CHALLENGER" THERMOMETERS[1]

II.

XI. *Accurate Measurement of Great Pressures.*

IT will be obvious from what has been said, especially as regards the old apparatus which was carried about in the *Challenger*, that one of the most essential requisites of the whole investigation was the accurate measurement of pressure. All the ordinary forms of pressure-gauge were found to be untrustworthy. It was necessary that in all cases the pressure should be measured with certainty to about 1 per cent. No attempt was made to secure any greater degree of accuracy, as the indications of the thermometers themselves could not in any case be trusted to less than 0°·1 Fahr.

The basis on which, after a great many trials, I finally founded my determination of pressures, was Amagat's[2] remarkable measurements of the volume of air and other gases at high pressures. Amagat's data were obtained in the most direct and satisfactory manner, inasmuch as he measured his pressures by means of an actual column of mercury extending sometimes to 300 metres, and more. All other means of measuring pressure are as it were valueless in comparison with this. We know by these experiments the compressibility of nitrogen, and of air, up to pressures of at least two and a half tons weight per square inch, with almost all desirable accuracy.

All that was necessary therefore in order to determine the pressures in the operating cylinder, and thus to calibrate the gauges employed, was to compress once for all a quantity of air, measure the volume to which it was compressed and the corresponding indications of the gauges, and then by the help of Amagat's tables compute the pressure actually attained. The apparatus I employed for this purpose is figured in section in the diagram below.

FIG. 4.—Air-gauge giving pressure (after Amagat).

This apparatus, filled with dry air, was allowed to come exactly to the temperature of the water inside the compression apparatus; then, the open lower end of it being dipped into a large vessel of mercury, it was let down full of air into the compression cylinder and pressure was applied. The effect was of course to compress the air, force up the mercury until it gradually filled the vessel and forced the air entirely into the smaller bulb. After a few trials we found roughly what amount of pressure was necessary in order just to commence the forcing of mercury into the small bulb. The mercury forced in was weighed; then the capacity of the small bulb was determined by weighing its contents in mercury. The difference of these weights is the weight of mercury, which would occupy the same volume as did the air when compressed. Finally, the original volume of the air was found by weighing the whole apparatus, first empty then filled with water; and, most important in view of Amagat's results, the barometer and thermometer were carefully observed at the instant when the apparatus had its lower end placed in the vessel of mercury. Mr. Kemp, who made these instruments for me, suggested and carried out the great improvement of inserting a small triangular pyramid of glass into the choked part of the bore (as shown in the small sketch). The effect is to break the mercury (which must be very clean) into exceedingly small drops. In this way the actual compression of the air was determined with a limit of error, represented at the utmost by the ratio of the volume of one of the small drops of mercury formed at the obstruction to the whole capacity of the small bulb. By working simultaneously with three instruments of this kind, even this very small error could be in great part eliminated:—and, practically, the compressions were measured far more accurately than was at all necessary for the purpose in hand. For greater accuracy a larger apparatus would be required. This, however, was quite unnecessary. And the requisite limit of accuracy in the experiment rendered it unnecessary to correct for the alteration of volume of the smaller bulb consequent on the pressure to which it was subjected.

In my later experiments a long carefully-gauged tube of 1·5 mm. in bore was substituted for the small bulb. This tube was coated internally with an excessively thin film of metallic silver thrown down by sugar of milk. The process was arrested the moment the film became visible by reflection. This film is at once dissolved by the mercury up to the point which it reaches at the greatest pressure, and leaves a perfectly sharp and nearly opaque edge from which to measure. This device has proved so very successful that I have now substituted it for the indices in all the pressure gauges (shortly to be described) which are employed for very accurate measures. And I am at present engaged in measuring, by comparison of a glass gauge and an air-gauge both filled in this manner, the compression of various gases at pressures up to fourfold those applied by Amagat.

XII. *Internal Pressure Gauges.*—The next step was to find some plan of construction for an instrument which, having its scale determined once for all by comparison with the air-gauge, should ever afterwards serve instead of it, thus affording a ready measure of pressure. Liquids are obviously better fitted for this purpose than solids, if only on account of their absolute homogeneity and their greater compressibility. But, unfortunately, *two* liquids must be employed, since a record must be kept:—the apparatus being surrounded on all sides by nine inches of iron:—and all my trials with two liquids were more or less unsatisfactory. The very fact that I was dealing with thermometers whose bulbs were protected from pressure, at once suggested an unprotected thermometer as something perfectly well suited to the purpose so long as the glass might be trusted to follow Hooke's law. [I have since found that the invention of such an instrument, to be used as an *élateromètre*, is due to Parrot.[1] His investigation of the effects of pressure is wholly incorrect, as it takes no account of distortion; but the device, and the recognition of the fact that its indications are proportional to the pressure, are wholly his.]

These instruments, which, like the thermometers, are fitted with a needle-index with hairs attached, have only one defect, which is that they act like thermometers as well as pressure-gauges. That defect I managed to remove almost completely by the simple device of inclosing in the bulb a closed glass tube which *all but* fills it. The liquid then occupies only a small space between the interior tube of glass and the exterior tube forming the bulb, and is as ready as ever to give indications of pressure, while it is not in sufficient volume to be more than slightly disturbed even by a serious change of temperature.

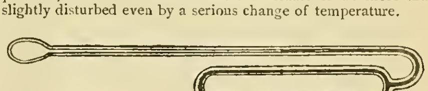

FIG. 5.—Internal gauge, plugged.

It is quite easy, by comparing two instruments of this kind in which the ratios of the internal to the external radius of the cylindrical bulb are different, to find by trial through what range its indications are strictly proportional to the pressure. Thus all the requisites of a perfect gauge, so far as the experiments required, were met by this simple apparatus. That I have obtained a sufficient accuracy in the graduation of these instruments is proved by the close agreement between my results for the volumes of air at different pressures as measured by means of them, with the volumes corresponding to these pressures in Amagat's table. If Boyle's law had been even approximately true for these high pressures, this mode of verification would have been fallacious. It would, however, be easy to make an independent verification, by sinking some of these instruments, each thoroughly imbedded in a mass of lard (as a protection

[1] By Prof. Tait. Abridged by the Author from a forthcoming volume of the Reports of the Voyage of H.M.S. *Challenger*, by permission of the Lords Commissioners of H.M. Treasury. Continued from p. 93.

[2] "Mémoire sur la Compressibilité des Gaz à des pressions élevées," par M. E.-H. Amagat (*Ann. de Chimie et de Physique*, 1880).

[1] "Expériences de forte compression sur divers corps, par M. Parrot" (*Mémoires de l'Académie Impériale des Sciences de St Petersbourg*, 6me. série, tome ii., 1833). The pages are headed "Parrot et Lenz," and it was by mere accident (seeking in the Royal Society's "Catalogue of Scientific Memoirs" for a reference to Lenz's thermo-electric writings) that I lit on the paper. I was much surprised at some of the statements it contains, till I found at the very end a footnote by Lenz, in which he disclaims all responsibility for the writing of the paper, and for the conclusions drawn in it.

from shocks) to a measured depth in the sea. This idea is worthy of consideration, especially if the gauge be made to register by means of a silvered tube. The only probable cause of error in such a case would be the breaking of the mercury column by a jerk, and to this all other forms are at least equally liable.

XIII. *External Pressure Gauge.*—But it was necessary not merely to measure accurately the pressure applied, but also, for the sake of the thermometers, to provide that the pressure should not be carried too far; and for that purpose it was indispensable to have an exterior indicator of pressure. This was furnished by a thin cylindrical steel tube inclosed in a cavity bored in a large block of iron, the interior of the steel tube being full of mercury and the narrow space between it and the large iron block also full of mercury. This exterior space was connected with the pressure apparatus. The pressure then throughout the whole of the space exterior to the steel cylinder was the pressure in the pump. The steel cylinder was therefore compressed from the outside. In the neck of the steel cylinder, which was screwed into the surface of the block, there was luted a vertical glass tube. It was exposed to no pressure, but the mercury in it rose, by the compression of the steel cylinder, and the height to which it rose could be easily measured. Comparative experiments were made several times by putting one of the glass gauges, whose scale had been carefully ascertained, inside the apparatus, while this newly-described gauge was also connected with it. In this way the external gauge was accurately calibrated. But, lest an accident should happen to one of the gauges, or to its index (as sometimes was the case) no experiment was made without the presence of at least three gauges. The way in which these worked together during the whole course of the experiments is the best possible proof of their value. This form of gauge, also, is greatly improved by inserting a glass tube closed at both ends into the bulb; for the temperature changes produced by pressure in mercury are greater than those in water at ordinary temperatures.

XIV. *Results of the Experiments. The True Correction for Pressure is very small.*—As soon as I applied pressure to the *Challenger* thermometers I found I reproduced pretty nearly the results obtained by Capt. Davis. I had already seen one proof that at least a large part of the result was in all probability not due directly to pressure. The experiment with the long thermometer tube showed that my theoretical calculations had been correct. The question thus became:—Is this a pressure effect of any kind; and, if so, how does it originate? and if it is not a direct pressure effect, to what is it due? There are many ways of answering such questions. One answer was furnished by one of the thermometers (A 3), whose degrees (especially on the maximum side) are very short. The whole effect (in degrees) on this thermometer was not very markedly greater for a given pressure than on the others, as it would certainly have been had the effect been entirely due to pressure directly. Another is, if it be not a direct pressure effect it must be a heating effect. With Sir Wyville Thomson's permission I got from Mr. Casella, the maker of the *Challenger* thermometers, a couple of others of exactly the same form and dimensions, but with the bulbs plugged after the manner of the gauges already described, so as to diminish their susceptibility to changes of temperature. When I put one of these into the pressure apparatus along with one of the *Challenger* thermometers, I found the effects on the new form very much smaller than on the old. Thus it was at once proved that the effect could not be due to wry neckedness produced by the fitting on of the protecting bulb; which would have been an effect due to pressure directly; but that it must be an effect due to heat. That is to say, it was now completely established that the large results obtained by Capt. Davis are due in the main to causes which can produce no effect when the thermometers are let down gradually into the deep sea; they are due to causes connected with the thermometers, and perhaps also with the pump, but solely under the circumstances of a laboratory experiment.

XV. *Sources of the large Effect obtained in the Press.*—Now comes the question (no longer important to the *Challenger* work, but of great scientific interest), What are these various sources, and how much of the effect is due to each? First of all we have seen that the water in the press is heated when pressure is applied. Using Sir William Thomson's formula I found the amount of that heating should be about 0°·05 F. at 43° F., 0°·16 at 50°, and only 0°·3 at 59°, for one ton of pressure. [These numbers are rather too small. We do not yet know to what extent the temperature of the maximum density point of water is lowered by pressure.] These cannot be expected to be fully shown under the circumstances of the experiments, and even if they were fully shown the greatest of them represents only about one-half of the whole of Capt. Davis' result; there must therefore be some other cause. [Prof. Tait then gives details of the various experiments by which he traced the sources of the large effect obtained.]

Thus it appears that there are no less than five different causes which contribute each its share to Capt. Davis' result. Of these, one is independent of the others, and would produce its full effect even if they were not present. The other four give effects which are not cumulative, and it would be very troublesome to try to assign to each its exact share of the result when two or more act together. Fortunately, it will be seen that we do not require to attempt to solve this problem.

(1.) First is the direct effect of the external pressure upon the exposed part of the thermometer tubes. This, in general, will be found very small, except in tubes where there are large aneurisms. The whole effect of 3 tons pressure on a *Challenger* thermometer without aneurisms, at temperatures near freezing point, so far as the minimum index is concerned, would be only about 3 one-thousandths of 30 degrees or so, that is 90 thousandths or at most 0·1 of a degree for 3 tons pressure. That is an amount which, in consequence of the necessary errors of reading the thermometers, may be entirely neglected, and, unless there are large aneurisms, there will be little need for pressure corrections even in six miles of sea.

The other parts of the observed effect were

(2.) Heating of water. This I observed to follow very nearly, according to Thomson's formula, the original temperature of the water. By comparing the pressure effects on the same thermometers during summer, and during winter (for which latter the late continued frost was of particular service, and enabled me to work for many days at the temperature of the maximum density of water), I found the results to vary in accordance with calculation.

(3.) Heat due to friction during pumping. This from its very nature was unavoidable unless we could have got an apparatus into which (by enormous pressure) the plug could have been forced directly. This could not, however, have been done in my laboratory, even if the apparatus had been adapted to such a form of experiment. But it was very easy to calculate the extreme possible amount of this effect.

(4.) The peculiar heating effect due to the vulcanite mounting. I verified this effect of vulcanite by taking a thermometer which had no vulcanite about it and measuring the effect produced upon it by a definite pressure, and then putting loosely round the bulb (in a test-tube, which had itself been previously experimented on) a small quantity of vulcanite in thin plates. I found that so little as 8 grammes of vulcanite round the protecting bulb raised the effect produced by a pressure of 3·2 tons weight from 0°·5 F. to 1°·1 F. The vulcanite was in thin strips about a millimetre and a half in thickness. The effect of the vulcanite on the *Challenger* thermometers (in the hydrostatic press) must, from the mode of their construction and mounting, in all cases be considerably greater than this.

Under these circumstances, we might without farther inquiry fairly attribute the whole outstanding effects to the massive vulcanite slabs on which these thermometers are framed. But there still remains

(5.) The most difficult question of all, the temperature effect produced by pressure upon the protecting bulb, which is under different circumstances altogether from the vulcanite; for the vulcanite is simply compressed, while the glass sheath is under pressure on one side and not on another, and is therefore subject to shear as well. In its interior the glass is extended in a radial and compressed in a tangential direction. Nobody has yet made any approximation to an answer to the question what effect in the way of heating or cooling will be produced by deformation which consists partly of compression and partly of change of form. We know that in indiarubber a cooling effect is produced by traction, and it may happen that a similar change of form in glass also produces a reduction of temperature. This is a question, however, which is not capable of answer by the help of my present apparatus;—though it will probably be answered by experiment before theory is able to touch it. The results of my experiments on the thermometers with plugged bulbs show that, on the whole, a heating effect results from the combined compression and shear in a bulb exposed to external pressure only. This has been verified by cutting down a thermometer, an exact counterpart of the *Challenger* thermometers

but without aneurisms, taking out the greater part of the mercury and inserting a second (now a maximum) index in the minimum side of the tube. When this instrument was stripped of its vulcanite, the effect of pressure at 40° Fahr. was considerably greater than that due to compression of the tube.

But it does not require to be taken into account so far as the *Challenger* thermometers are concerned.

XVI. *Final Conclusion from the Investigation.*—The final conclusion is that only one of these five causes, which are active in the laboratory experiment, can affect the *Challenger* thermometers when let down into the sea, namely, pressure. There is there no heating of water by compression; there is no heating by pumping; there is no heating of vulcanite, because the thermometers are let down so quickly in comparison with the rate of increase of pressure that each little rise of temperature is at once done away with as the thermometer passes through a few additional yards of water; and the effect on the protecting glass also, for the same reason, which is a heating effect on the whole, is all but done away with step by step as it is produced. All these four causes, therefore, which made Capt. Davis' correction so much too large, are valid only for experiments in a laboratory press, and not for experiments in the deep sea. Therefore, as a final conclusion, I assert that, if the *Challenger* thermometers had had no aneurisms, the amount of correction to be applied to the minimum index would have been somewhat less than 0°·05 F. for every ton of pressure, *i.e.* for every mile of depth. All the thermometers which have large aneurisms have had special calculations made for them, but in no case does the correction to be applied to the minimum index exceed 0°·14 or about one-seventh of a degree per mile of depth.

[From] the *Appendices* to Prof. Tait's Report, which contain numerous formulæ with detailed descriptions of apparatus and modes of experimenting, we make the few following extracts.]

The diminution per unit volume of the interior of a cylinder with closed ends, of internal radius a_0, and external radius a_1, when exposed to an external pressure Π, is

$$\Pi\frac{a_1^2}{a_1^2 - a_0^2}\left(\frac{1}{n}+\frac{1}{k}\right).$$

Here n is the rigidity, and $\frac{1}{k}$ the compressibility, of the walls of the cylinder.

When Π is a ton-weight per square inch, the value of the quantity

$$\Pi\left(\frac{1}{n}+\frac{1}{k}\right),$$

is, according to the best determinations, somewhere about $\frac{1}{1000}$ for ordinary specimens of flint glass, and about $\frac{1}{1000}$ for steel. This expression is very simple, and enables us at once to calculate the requisite length of bulb, when its internal and external radii are known, which shall have any assigned sensitiveness when fitted with a fine tube of a given bore. To obtain great sensitiveness, increasing the diameter of the bulb is preferable to diminishing its thickness, as we thus preserve its strength; and we have seen how to avoid the complication of temperature corrections.

As a verification of this formula, in addition to the simple one described in the text above, I had an apparatus constructed of ordinary lead glass of the following dimensions:—Length of cylindrical bulb, 745 mm. Ratio $a_0 : a_1 = 8·7 : 21·9$. The weight of mercury filling 424 mm. of this bulb was 167 grm. To the bulb was attached a smaller tube of which the mercury filling 68 mm. weighed 1·43 grm.

Hence we have

$$\frac{a_1^2}{a_1^2 - a_0^2} = 1·187.$$

Also the content of the whole bulb in mercury is $\frac{745}{424}167$ grm. = 293·4 grm. Hence a pressure of one ton-weight should force into the narrow tube $\left(\frac{1·187}{1000}293·4 =\right)$ 0·348 grm. of mercury. This ought to displace the index through $\left(\frac{0·348}{1·43}68 =\right)$ 16mm.·55.

Comparing this with the result of experiment, we had the following remarkably satisfactory numbers:—

Tons.		Calculated.		Observed.
0·9	...	14·9	...	14·6
1·4	...	23·1	...	21·2
3·1	...	51·3	...	48·9

There was no glass tube in the interior of the bulb, so that the slight discrepancies between the ratios of calculated to observed effects are mainly due to effects of temperature.

In the *Proc.* R.S., June, 1857, Sir William Thomson gives for the rise of temperature of a fluid, the pressure on which is suddenly raised from p to $p + \omega$, the general expression

$$\frac{te}{JK}\omega.$$

Here t is the absolute temperature of the fluid; e its coefficient of expansion, and K its average capacity for heat, under constant pressure, between p and $p+\omega$. J is Joule's equivalent.

The value of e, as given by Kopp's experiments, is nearly

$$\frac{t-278}{72,000},$$

for temperatures within 20° C. of the maximum density point. The mean of the experimental determinations of Matthiessen, Pierre, and Hagen, makes it about 5 or 6 per cent. greater.

For the Centigrade scale the value of J is 1390 foot-lbs. An atmosphere of pressure is nearly 2117 lbs. weight per square foot; and K is about 63·45 (the number of pounds of water in a cubic foot).

Hence it follows that, for one additional atmosphere of pressure, the temperature of water is raised (in degrees Centigrade) by about

$$\frac{t(t-278)}{2,850,000}.$$

Now 56° F. is 13°·3 C., for which $t = 287·3$, and the rise of temperature produced by a ton-weight per square inch is

0°·14 C. or 0°·25 F.

This is the statement in the text.

From the above formula we find the heating effect of one ton pressure on water at 50° F. to be nearly

0°·16 F.;

and for each degree above or below 50° F. this number must be increased or diminished by about one-tenth of its amount.

This expression is very easy to recollect, and it gives the results with ample accuracy throughout the whole range of temperatures (40°–60° F.) within which my experiments were conducted.

It is to be observed that Thomson's formula is strictly true for small pressures only. No account has been taken of a possible lowering of the temperature of maximum density, or of a change of expansibility, under pressure. Nor is it known how a considerable increase of pressure affects the thermal capacity.

On the first occasion on which one of the thermometers gave way, we were much surprised at the loudness and musical quality of the sound produced. The whole mass of iron and steel vibrated like a bell in consequence of the (comparatively slight) sudden relaxation of pressure. On another occasion, just as a pressure of three and a half tons had been reached, the whole apparatus gave a strong, protracted musical sound, which continued until the screw-tap was opened. This was probably due to a species of hydraulic-ram behaviour on the part of one of the valves of the pump. These are little conical pieces of steel, with the points much elongated, which are ground accurately into conical beds, and fall back into their places by gravity. It was not observed that this powerful vibration had in the least degree altered the position of the indices in the thermometers or gauges which were in the pressure chamber. Their indications agreed perfectly with those of the preceding and succeeding day.

I made a number of experiments with the view of determining the amount of distortion at which glass gives way, with the view of finding the limit of strength of a glass tube, and also the ratio of external to internal diameter to secure it against any assigned lower pressure. I allude to them now in consequence of a curious fact observed, which gives the explanation of a singular occurrence noticed on board the *Challenger*. The walls of the tubes, when they gave way, were crushed into fine powder, which gave a milky appearance to the water in the compression apparatus. But the fragments of the ends were larger, and gave much annoyance by preventing the valves of the apparatus from closing. To remedy this inconvenience, I inclosed the glass tube in a tube of stout brass, closed at the bottom only, but was surprised to find that it was crushed almost flat on the first trial. This was evidently due to the fact that water is compressible, and therefore the relaxation of pressure (produced by the break-

ing of the glass tube) takes time to travel from the inside to the outside of the brass tube; so that for about 1-100coth of a second that tube was exposed to a pressure of four or five tons weight per square inch on its outer surface, and no pressure on the inner. The impulsive pressure on the bottom of the tube projected it upwards, so that it stuck in the tallow which fills the hollow of the steel-plug. Even a piece of gun-barrel, which I substituted for the brass tube, was cracked, and an iron disk, tightly screwed into the bottom of it to close it, was blown in. I have since used a portion of a thicker gun barrel, and have had the end welded in. But I feel sure that an impulsive pressure of ten or twelve tons weight would seriously damage even this. These remarks seem to be of some interest on several grounds, for they not only explain the crushing of the open copper cases of those of the *Challenger* thermometers which gave way at the bottom of the sea, but they also give a hint explanatory of the very remarkable effects of dynamite and other explosives when fired in the open air.

To show how possible is a serious mistake in the measurement of pressure, I append a comparison of the indications of the very elaborate gauge attached to the old *Challenger* apparatus with those of my steel external gauge already described. The scale of the *Challenger* gauge is divided to cwts. on the square inch. My gauge gives very nearly 20 mm. per ton; so that, for a rough comparison, we may take 1 mm. as equivalent to 1 cwt. The two instruments were simultaneously attached to the pump, and the pressure was therefore the same in both at each reading. There can be no doubt whatever, from repeated comparisons with glass gauges of all sizes and shapes, that my gauge follows Hooke's law with great accuracy. The only possibility of serious error is in the actual value of the unit. This important determination has, however, been very carefully repeated by the aid of Amagat's numbers and the indications of the silvered gauge already described; and the result is as above stated.

Steel Gauge. Millimetres.	*Challenger* Gauge. Cwts. per sq. in.	Ratio.
0	0	...
5	0	0·0
9	1·2	0·13
15	8·7	0·58
20	13·9	0·69
30	23·6	0·78
40	35·0	0·87
50	47·0	0·94
60	58·7	0·98
70	71·7	1·02

The comparison was repeated several times with almost exactly the same results.

It is quite clear that the *Challenger* gauge does not follow Hooke's law. It lags behind the steel gauge at first (does not give any indication, in fact, till the pressure is nearly 50 atmospheres), then gradually gains on it; and, at pressures greater than 3½ tons, appears to leave it rapidly behind. The instrument is, however, graduated up to 4 tons only. My very first experiments with this *Challenger* instrument, in which I used a simple form of manometer, showed that it was not trustworthy, and led me to make various trials for the purpose of getting a proper mode of measuring high pressures.

Finally, it may be interesting to mention that a fairly approximate determination of the compressibility of water was made by counting the number of strokes of the pump required to produce a measured pressure in the interior of the large apparatus.

[Then follows a table of the experimental data for each of a large series of the *Challenger* thermometers. These are of no general interest. Their importance is confined to the reduction of the actual observations made on board the *Challenger*].

THE GRASS BARRIERS OF THE NILE

THIS interesting phenomenon, which so largely contributes to produce changes in the bed of the Nile and to accumulate river formations of great geological importance, has been recently investigated by M. Ernest Marno, who has just published an elaborate paper on the subject, in the last number of *Petermann's Mittheilungen*. It is accompanied by a map, on the scale of 1 to 500,000, of the Bahr-el-Gebel and of the Bahr-el-Abiad, from Geseir Abbas to Sohat, and of the Bahr-el-Serat from its mouth to 7° 30′ N. lat. After having made its way among the hilly region, through several great lakes, formerly forming a series of terraces and connected together by short rivers, the Nile, or the Bahr-el-Gebel—the River of the Mountains—enters an extensive flat land, which it crosses over six degrees of latitude to the next rocky barrier, which it cuts through at Khartum. Over this stretch it runs with numerous windings, first north to its confluence with the Bahr-el-Ghazal, and then to the east, under the name of Bahr-el-Abiad, and, although the direct distance between its issue from the hilly tract to Khartum is only 600 miles, the total length of the river with its windings is no less than 1100 miles. The whole of this region is a wide marsh, and the river has no proper banks, its water being mixed with that of marshes which cover the whole of this tract. It is even a rare occurrence to see dry banks, as the country is more like an extensive marsh, through the midst of which a somewhat deeper channel has been dug by the current of the river. Numerous smaller rivers connected together and with the main channel and its numerous ramifications circulate amidst these marshes, and during the rainy season the *maije*, or lateral ponds and lakes, increase yet more, covering wide tracts of land, whilst during the dry season some stretches of banks re-appear, and the lakes which were navigated by steamers some months before become simple marshes. Vegetation plays an important part in the modifications which are going on in this region. The country is covered with rich grasses, mostly consisting of such species (*Saccharum spontaneum*, *S. irschæmum*, *Vossia*) as grow perfectly well even in water; this grass can be lifted with its roots by water, and grow floating on the surface, so as to render it most difficult to draw a line of demarcation between land and water. Thick and high papyrus palms grow sometimes on the very banks of the main channels of circulation of the water, and strengthen these by their complicated roots, but they do not cover all the banks, and the outlines of the river are mostly indefinite. Some few tree-like *Herminiera elaphrosylon* grow as isolated individuals on the banks of the rivers, and of the *maije*, whilst the smaller marshy and aquatic flora (*Pistiæ*, *Nymphеæ*, *Vallisneriæ*) nearly disappears in comparison with the rich vegetation of the above-named species. The fauna of this region closely depends upon the season. Mammals and birds leave it during the rainy period and wander to the hilly tracts, but during the dry season the banks of the *maije* and of the rivers are peopled with elephants, buffaloes, giraffes, antelopes, and by many kinds of birds. Besides this region has also its special forms, namely the *Balæniceps Rex*, the *Protopterus æthiopicus*, and the ganoid fish, *Polypterus*, all being remains from earlier geological periods. The people who inhabit this region, the Dinka, the Shilluk, and the Nuehr, all belong to a very low level of civilisation, living mostly on their herds of cattle; they change their abodes in accordance with the season, but they cannot be considered as true nomades, as the land occupied by each tribe is strictly limited by other tribes, and every encroachment on another's land is punished by war.

It is obvious that in this region the fall of the rivers is very small and that the regular outflow of water may be checked by winds and other occasional circumstances; whilst the great quantities of water poured down into the basin during the rainy season cannot find an easy way through the flat channels; extensive inundations occur therefore every year, and when the rains are especially heavy, great masses of floating grass are brought from the *maije* into the main river, and accumulate in its windings. New floating islands of grass are brought by and by to these barriers, being pressed upon or beneath them, and soon the whole of the river throughout its width and depth is obstructed by these barriers, which the inhabitants call *setts*. The grass does not decay in

the *setts*, it continues to grow on their surface, and if the vegetation, which rises two or three metres above the water, is burnt, it soon reappears again, reaching a height of one metre and more after eight or ten days. The thread-like roots of the grass form a kind of rough felt, in which palms are sometimes inclosed, whilst masses of ooze fill up the interstices between the roots, and form thus true dams across the river. When the barrier has not yet reached a great size, it might be occasionally destroyed by the pressure of water accumulated above it; but, as several barriers are formed at the same time at various places, the upper one being destroyed, its *débris* is brought to the lower one, and accumulates above it, or presses beneath it. The elasticity and tenacity of these dams is so great that a steamer attempting to enter it is soon repelled by the elasticity of the grass, while men and even cattle can easily stay on the floating grass without danger. The river is thus soon transformed into a marsh covered with a mighty grass vegetation, and the water expands to the neighbouring *maije*, seeking its way through many new channels. It is obvious that those parts of the river where its bed is more definite are especially liable to be obstructed by grass islands which are formed in those parts of it where there is no definite frontier between running water and marsh. As to the appearance of *setts*, M. Marno is of opinion that they have become more frequent during these last years; he sees in their frequency a proof of the gradual levelling of the whole region by fluviatile deposits and of the general transformation of the whole of the region into marshes. The high floods of 1878 have largely contributed to the formation of numerous floating grass islands and to the formation of several large barriers across the river. Of course any hydrographical works for preventing the formation of grass obstructions would be very difficult now, owing to the scarcity of population; but the planting of papyrus palms along the banks of the chief channel would be most useful, as it would prevent the floating grass islands formed in the *maije* from entering into the main channel of the Nile.

THE WEATHER OF NOVEMBER, 1881

THE weather of November last has been in many respects so unusual as to call for a brief record of its chief characteristics. For thirteen months previously the immense majority of the depression-centres, or centres of the storms which swept across North-Western Europe, passed to the southward of the northern half of the British Islands, and many of them wholly to the south of these islands, with the inevitable result of unseasonably cold weather to the north of these storm tracts. But early in November an important change set in, and up to the time of going to press the change has been an enduring one, viz. the storms of North-Western Europe have swept eastward along tracts wholly to the westward and northward of the British Islands, with the necessary result of a temperature very greatly in excess of the average of the month.

From Buchan's isobars for the month we see that the mean increase of atmospheric pressure from the Butt of Lewis to Valentia, in the south-west of Ireland, is about 0·100 inch; but in November last the increase amounted to 0·348 inch, the means of these places being respectively 29·391 inches and 29·739 inches. The increase from the Butt of Lewes to Dover was still greater, amounting to no less than 0·605 inch, instead of 0·150 inch, the normal difference. It is premature to state the locus of the centre of this extraordinary barometric depression till fuller observations have been received; in the meantime, however, a position in the Atlantic, a little to westward of the Hebrides, may be provisionally assumed as the centre with but a small limit of error.

The most important result of this abnormal diminution of atmospheric pressure in the north-west, and rapid increase southward, has been a prevalence of winds from the Atlantic, characterised by a force and a persistency quite unprecedented during the last quarter of a century, with a distribution of temperature and rainfall over the British Islands very remarkable and in some respects strikingly abnormal. As these winds from the Atlantic swept across and reached the east of Scotland, their direction took a more southerly, and in the north a more south-easterly course.

Everywhere the temperature was abnormally in excess—the smallest excess, about 3°·5, being on the coast in the north; and the largest excess being in the interior, as happens with high temperatures at this time of the year, since in such circumstances the cooling through terrestrial radiation is relatively much less than usual in strictly inland situations. The greatest excess would appear to have occurred in the higher parts of the valleys of the Thames and Trent in England, and of the Clyde and Tweed in Scotland, where it reached, or closely approached to, 6°·5 above the means of November for the respective districts. In London and Edinburgh the excess was 6°·0.

On comparing this excess for Edinburgh with the observations made in that division of the British Islands during the past 118 years, or since 1764, the mean temperature of November, 1881, is absolutely the warmest on record, the nearest to it being an excess of 5°·5 in 1818, and 5°·2 in 1792 and 1847. As regards London, the temperature of November 1818 and 1852 somewhat exceeded that of 1881, the former of these years being also unusually warm in Edinburgh, whereas there November, 1852, was colder than the average.

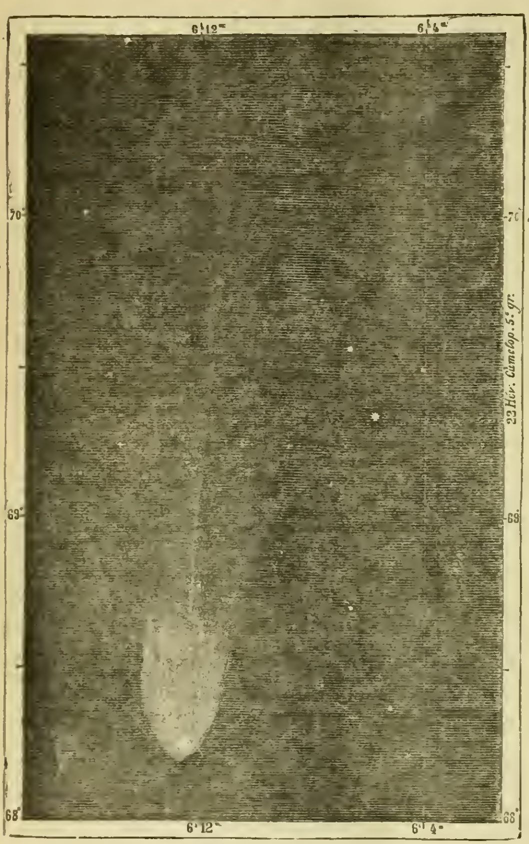
The distribution of the rainfall was strikingly unequal in North Britain, or where the prevailing winds curved round more towards a southerly and south-easterly direction. On the high ground sloping up on both sides to the Lead and Lowther Hills the rainfall at many places considerably exceeded double the average of the month. On the other hand to the north of the Cheviots and Lammermoors the rainfall was under the average, the amount in East Lothian being less than half the average. Crossing the Firth of Forth, we meet an extensive tract reaching as far as the high grounds of the Grampians, where the rainfall was excessive, amounting in West Perthshire and Upper Dee to more than double the average. Again, beyond the Grampians, and including the whole of the North of Scotland, northward and westward to the extreme north of the Lewis, the fall was less than the average, the amount on the south shores of the Moray Firth being only half the average. It is worthy of remark that this distribution of the rainfall is precisely the opposite of what occurs with weather very similar, but with the single difference of the south and south-east winds being replaced by north and north-east winds, in which the foreshores of the Forth, Moray, and Pentland Firths facing the north are deluged with rains. In the east of England the rainfall was, generally speaking, light, but it was above the average in Ireland, and in a less degree in the west of England.

Out in the Atlantic, along the great routes of traffic to New York, the month would appear to have been characterised by an almost unbroken succession of storms, several of which, if judged by their destructive effects on even well-appointed sailing-vessels and steamers, were memorably great storms. The storm which reached the west on the 21st will be long remembered for the furious winds and extraordinarily high and destructive tides which accompanied it; and the storm of Sunday, the 27th, for its most disastrous effects, particularly in the south, and for the unprecedentedly low readings of the barometer in the north-west and north of Scotland, where, over a wide area and for a considerable time, atmo-

spheric pressure was under 28·000 inches, the lowest being 27·865 inches at the Butt of Lewis, at which low point the barometer stood from 4.30 to 7 a.m. of the 27th.

PHOTOGRAPH OF COMET B, 1881

PHOTOGRAPHY has already proved of great service to astronomy, and its value in reproducing with unfailing accuracy and permanently preserving an observation is evident. It is long since the art has been utilised in the observation of eclipses; with De La Rue's



Facsimile of a photograph of the Great Comet B 1881, taken at the Observatory of Meudon, July 1, 1881.

photographs of the moon we are all familiar, while those of sun-spots have recently attained a rare degree of perfection. And now at last photography has been successfully applied to comets by Dr. Janssen at the Meudon Observatory, Paris. The woodcut we give to-day of Comet B is from our French contemporary *La Nature*, and has been revised by Dr. Janssen himself, so that it may be accepted as a faithful reproduction of his photograph. Dr. Janssen also gives some interesting details as to the circumstances under which the photograph of the comet was taken. It was obtained on July 1, 1881, at 0h. 37m. under the following conditions:—The operators used a telescope of half a metre aperture and 1·60m. focal length. The plates of gelatino-bromide of silver, extra sensitive, were manipulated and developed in darkness. The time of exposure was thirty minutes. Arrangements were made to counteract the proper movement of the comet in addition to the diurnal movement. The impression of the tail extends to more than 2½ degrees; and the head of the comet assumed very great dimensions; but the details of the tail show that the movement of the instrument has kept pace with that of the object. The rectilineal rays are a revelation of the photograph, which moreover shows some very small stars not seen in any celestial atlas.

ON ARTIFICIAL DEFORMATION OF THE HUMAN SKULL IN THE MALAY ARCHIPELAGO

MR. CROCKER mentioned, in the *Proceedings* of the Royal Geographical Society of London in the beginning of this year, that the Milanows, a coast tribe in North-West Borneo, between Bruni and Tandjong Agri, Sarawak, flatten their heads by means of pressure in infancy, but not to the extent of disfigurement, a custom, Mr. Crocker adds, which is peculiar to this tribe, and occurs nowhere else in the Archipelago.

This last statement induces me to show that, on the contrary, the custom is spread through the whole vast area from Sumatra to Timorlaut, and north to the Philippines; I even believe that it is not going too far to say that almost no large island within this region can be found, where the custom of artificial deformation of the skull is not, or has not been in use. Having treated of the geographical distribution of the custom all over the globe in a paper "Ueber künstlich-deformirte Schädel von Borneo und Mindanao im königl. anthropologischen Museum zu Dresden, nebst Bemerkungen über die Verbreitung der Sitte der künstlichen Schädel-Deformation," I shall restrict myself here to the Malay Archipelago.

To begin with Borneo: I procured last year a skull from Sarawak, over which a basket of ratan was so closely twisted, that it could but with difficulty be freed. When taken out I immediately perceived that it must have been artificially deformed; the whole occiput was flattened in a way which could not have been due to other causes. This skull (Fig. 1) must have hung a long time in the basket over a fireplace, for it was blackened and dusty all over. The direction of the pressure in youth had been, besides perpendicularly from behind, from the right side and below, for the right basal portion is totally distorted.

Wishing to know something positive as to the custom in Borneo, I wrote to the well-known naturalist and collector, Mr. Everett, who is now living in Papan, North Borneo, and who sojourned a long time in Sarawak before. Mr. Everett had the kindness to answer, in a letter dated August 25, 1880: "With regard to the custom of flattening the skull, I have heard that it is

practised by the Kanowits and Malanau tribes in Sarawak." In consequence of this information I asked Mr. C. C. de Crespigny of Sarawak, a gentleman who has already (in 1876) published some account of the Malanaus in the *Journal* of the Anthropological Institute of Great Britain, to forward, if possible, the instrument with

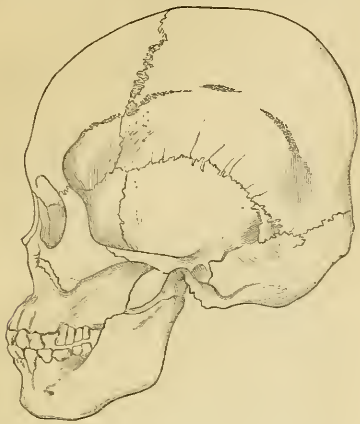


FIG. 1.—Artificially deformed skull from Sarawak, Borneo.

which the artificial deformation is effected; and Mr. de Crespigny was so obliging as to fulfil my wish and to write on April 8, 1881: "I am sending by this post the little instrument you desired me to procure for you, used by the Malanau women in flattening the heads of their female children, in order that their appearance may correspond with their parents' idea of beauty."

The instrument (Fig. 2) is by no means roughly made, but so well adapted to the purpose that one must regard it as the result of the exertions of many generations. I am sorry that Mr. de Crespigny, to whom I am so much indebted, did not add a note as to the way in which the apparatus is applied to the child's head. I suppose that this is wrapped up in cushions and laid with the occiput on the square wooden part of the apparatus *a*; the bandage *b*, made of blue cotton, then being tied round the forehead, the bandage *c* over the whole head from the forehead to the occiput, and the threads, fastened at the end of *c*, drawn through the holes in *a*, and finally through the square hole of a Chinese coin, behind which they are knotted together with some glass beads. Two sets of holes in the longitudinal part of the wooden instrument allow the degree of pressure to be regulated. The apparatus is very accurately cut and polished. The length is 325 millimetres, length and breadth of the square middle part 90 and 60 mm. respectively, the length of the frontal band 315, of the sagittal band 190 mm.

In the mean time Prof. Flower, in his interesting essay ("Nature Series"), "Fashion in Deformity, as illustrated in the Customs of Barbarous and Civilised Races," mentioned, on the authority of Mr. H. B. Low, that in the neighbourhood of Sarawak the deformations are made purposely; and I therefore do not doubt that the custom is a common one in that country. Perhaps a very asymmetrical skull in the Vrolik collection of Amsterdam, from Banjermassin in South-Eastern Borneo, may be artificially deformed. I have not yet succeeded in finding another trustworthy report of the same custom in Borneo from other tribes, but am sure that we shall soon hear from other quarters of the same, attention once being directed to the question.

Proceeding from Borneo to the Philippine Islands in the north, we have ample materials from that group of islands. I procured, in the year 1872, in the island of

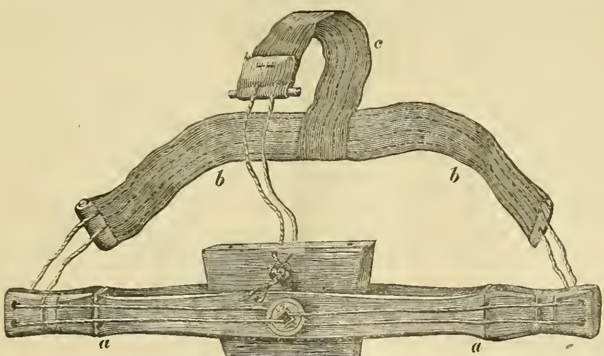

FIG. 2.—Instrument for deforming the heads of infants, used by the Malanaus on Borneo.

Luzon, in the province of Bataan in Zambales, from graves in the forest, twelve skulls of Negritos, nearly all of which are more or less artificially deformed. Prof. Virchow is of opinion that the flattening of the occiput and the broadening of the hinder parts of some of the skulls is so strong as to make them in a high degree similar to certain deformed skulls from Peru. The flattening of the occiput is very obvious in some of the portraits of Negritos which I sketched on the spot, three of which are represented in Figs. 3–5.

It has been known since the seventeenth century that the custom is in vogue on the Philippine Islands. M. Thévenot in his valuable work, "Relations de divers Voyages curieux" (1664), in the part, "Relation des isles Philippines faite par un Religieux qui y a demeuré 18 ans," says in his old French: "Ils auoient accoustumé dans quelques-vnes de ces Isles, de mettre entre-deux ais la teste de leurs enfans, quand ils venoient au monde, et la pressoient ainsi, afin qu'elle ne demeura pas ronde, mais qu'elle s'estendit en long; ils luys aplatissoient aussi

le front, croyant que c'estoit vn trait de beauté le a'auoir ainsi." Artificially deformed skulls have further been procured by Doctors Schetelig and Jagor, about the year 1860, from caves on the islands of Samar, Leyte, and Luzon, and from Bicol and Cimarron graves (Cimarrons being hybrids between Negritos and Bicols) in Albay on Luzon. An Igorrotes skull from West Luzon, which I brought home, is, according to Prof. Virchow, so small as to suggest that it has not its natural form. From the south-west of the large island of Mindanao Professors de Quatrefages and Hamy have described two deformed Hilloonas (Negrito?) skulls, and the Dresden Museum possesses two enormously deformed skulls from a cave

FIG. 3.

FIG. 4.

FIG. 3.—Negrito, man, Luzon. FIG. 4.—Negrito, young woman, Luzon.

near Lianga in South-East Mindanao, procured by Prof. Semper.

One of these (Fig. 6) has been pressed from the front to the occiput for the special purpose, at the same time, of flattening the whole head. The hinder parts of the parietals slope down nearly perpendicularly at the tubera, and the occiput has no prominence at all. The other (Fig. 7) has been acted upon from below and behind and from the front, and, at the same time, by a broad bandage across the parietals behind the coronal suture, where a deep depression occurs. The tubera parietalia are blown up similar to those of skulls from the Gulf of Mexico,

FIG. 5.—Negrito, man, Luzon.

which Dr. Gosse called "têtes trilobées." Therefore it cannot be doubted that the custom has been, and is in use nearly everywhere on the Philippine Islands.

Not less so in the island of Celebes, which is nearly united to the Mindanao by some smaller groups of islands, which may be considered as stepping-stones. Mr. Riedel of Gorontalo informed us in the year 1871 that the inhabitants of Buol, Kaidipan, and Bolang-itam in North Celebes wind round the heads of their children the smoothed bark of the Lahendong tree, and afterwards press it between two wooden planks, which are fastened in front and occiput. The heads are broadened by this process, which is considered a peculiar attraction; the child is treated in this way from four to five months. Mr. Riedel even forwarded a model of a cradle, as used in Buol for deforming the heads of noblemen's children; the instrument remains fastened for six to eight weeks, and the children are only freed every second day to be bathed. Mr. Wilken recorded the same custom from

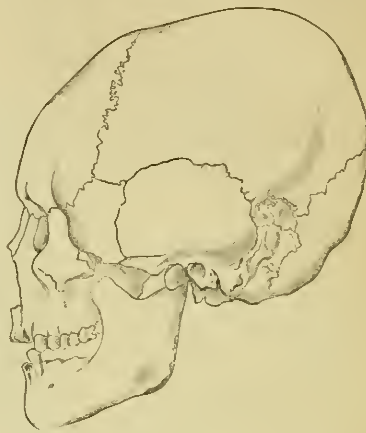

FIG. 6.—Artificially deformed skull from a cave near Lianga, Mindanao.

Passan and Ratahan in the Minahassa, in North Celebes, the last-named spot being quite near Panghu, a place where Mr. Wallace made one of his celebrated collections ("Malay Archipelago," vol. i. p. 408). Mr. Wilken says that the process is continued from fifty to sixty days, and that the flattening of the forehead is called "taleran," the common people practising it very generally now. The

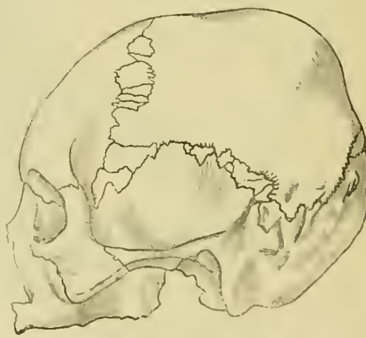

FIG. 7.—Artificially deformed skull from a cave near Lianga, Mindanao.

same custom is in use still with other tribes of the Minahassa and the surrounding countries. Finally, Mr. Riedel could prove it among peoples called Toragi, Tondai, Torau, and Tomori in Central Celebes, where the heads of the boys are pressed laterally and from behind, "that they may become good warriors," and the foreheads of the girls broadened "to increase the beauty of the

women"; the process is continued from four to five months.

Besides this direct information there is an artificially deformed skull of an "Alifuru," from Celebes in the Hildesheim Museum; and of a Bugis from South Celebes, in the Vrolik Collection of Amsterdam, the descriptive catalogue saying: "Plus que tout autre ce crâne fait l'effet d'avoir été comprimé à son jeune âge par une grande force agissant d'arrière en avant." Dr. Barnard Davis remarks on a skull from Makassar, in South Celebes: "Has an extensive parieto-occipital flattening; the result is a brachycephalism which scarcely seems compatible with undesignedness." No doubt this is proof enough to justify the opinion that the custom is spread over the whole island of Celebes.

As to Sumatra Marsden has often been quoted, "that the women have the custom of compressing the heads of children newly born, whilst the skull is cartilaginous, which increases their natural tendency to that shape."

From Java it has been made known by Professors van der Hoeven, Swaving, Halbertsma, and Zuckerkandl, that a considerable proportion of the skulls from that island are asymmetrical, viz. 60 per cent., and that of three awry skulls two are flattened on the left side. Prof. Halbertsma supposes that this asymmetry comes from the child's position on its left side while sleeping; Prof. Zuckerkandl is of opinion that it comes from pressure during birth; whereas Prof. Rolleston, whose premature death we deeply deplore, expressed the following view:—"The wish to keep the right arm free causes the left arm to be usually employed for carrying a child; the pressure of a sling used in aid of the left arm would come to bear mainly on the left side of the child's head, and the observed flattening would thus be accounted for." However this may be, the asymmetry does not appear to occur as a result of designed deformation; but Dr. Swaving concedes that the midwives try to change the form of the head in the newly-born child by pressure; Dr. Gosse saw a Javanese skull with occipito-nasal deformation, and perhaps this question must be more thoroughly studied on the spot to get a better insight.

Dr. Davis says of a skull from the island of Bali:—"Approaches closely to the American crania deformed by occipito-frontal pressure; it is so great as to render it very difficult to look upon the distortion as unintentional."

The Dresden Museum possesses a skull from the island of Ceram, and another one from Boano, near Ceram, which appear to be artificially deformed; further, two skulls of the same kind from the island of Flores among ten specimens. Of a skull from the island of Timor, Dr. Davis says: "Of extraordinary form and proportions, being extremely brachycephalic, and exhibiting a large parieto-occipital flattening." Finally, the Dresden Museum recently got from the Timorlaut Island group two skulls which undoubtedly are artificially deformed.

I will not proceed further on to New Guinea, because this would lead me into the Papuan or Melanesian region, where, as well as on many islands of the South Sea, the custom prevails; but I only proposed to show its being far spread through the Malay Archipelago. I do not doubt that more information will come from this region, if only the attention of residents and explorers in future is directed to the question, and if more skulls are forwarded to scientific men and institutions.

A. B. MEYER

NOTES

EVERYTHING in connection with the Crystal Palace Electrical Exhibition appears to be progressing most satisfactorily. All the available space has been allotted to exhibitors, and many applications for room have had to be refused. The best positions have been given to the first applicants, and from appearances there is little doubt but that this exhibition will be a success. As an Electric Light Exhibition it will surpass that in Paris, because the peculiarities of the building permit direct comparisons being made, and allow of each different system having a portion of the building allotted to itself. Thus the whole of the nave will be divided off, each part to a different system, while all the different courts, the Alhambra Court, the Pompeian Court, and others, will have a separate and distinct system applied to its illumination. There does not appear to be in the world a building more suited for the display of the electric light than the Crystal Palace with the far-famed courts referred to. There is little hope of any show being made before the commencement of the ensuing year, but there is strong reason to believe that some portion of the building will be illuminated by the electric light at Christmas time. Not only has the Postmaster-General consented to make an extensive show, but the War Department have now agreed to exhibit, and there is every probability that this display will be most interesting. Had our War Department made an exhibition in Paris it would have undoubtedly outshone the displays of other governments in this section. A great feature of the exhibition will be the external exhibits. A tramway is about to be constructed along the whole terrace, on which a coach will run by the aid of Faure batteries. An electric railway, which was such an attraction at Paris, will continue to whirl passengers about by the energy produced by Siemens' currents. Although the exhibition will contain a great display of apparatus relating to all the applications of electricity, it will be an Electric Ligh Exhibition, and the numerous lamps and machines for the production of the light will be the great attraction to the public.

MR. LIVINGSTONE, Master of the Public Schools, Fort William, having kindly offered to the Scottish Meteorological Society to climb Ben Nevis once a month, whenever practicable, to read the thermometers left on the top of the Ben, made his first ascent on Saturday last. He left Fort William at 8.15 a.m., and returned at 4.5 p.m. The ascent to 2200 feet was easily accomplished, the real difficulties being encountered above this height, owing to the snow which covered the higher parts of the Ben. A shower of rain fell at the lake on the way up. At this point, as had been done by Mr. Wragge, observations were taken, and the temperature of the air found to be 37°·0, and that of the water 38°·3. On reaching the spring, which is 3363 feet high, the temperature of the air was 30°·0, and that of the spring 35°·6, or a degree higher than in the middle of June. The summit was reached at 1 p.m., the wind being north-west the temperature of the air 26°·5, and the plateau covered with snow to a depth of 2 feet. The protecting cage for the thermometers and other instruments was found all right. The maximum thermometer read 44°·0, and the minimum 14°·1—these being the extremes of temperature since Mr. Wragge made his last observation in the end of October.

IN a few days the Russian expedition to the mouth of the Lena to establish a magnetical and meteorological observatory on Weyprecht's plan is to start from St. Petersburg. The route is by rail to Nishni-Novgorod, thence by sleigh to Perm, by rail to Yekaterineburg, by sleigh to Irkutsk, where they are expected to arrive in January, and stay till May to complete their outfit, secure the services of five soldiers, and train them to meteorological observation. Meanwhile a barge is to be built or bought at Katschug, on the Lena, where the navigation of this river begins. The party, on descending the river, will stop for some time at Irkutsk, to make further preparations. The length of the route, and especially the difficulty of transportation by land without railways, make the Russian expedition the most difficult of the Arctic expeditions on Weyprecht's plan. Petroleum is wanted to give a good, clear light, and $2\frac{1}{4}$ tons of it will

have to be bought at Nishni-Novgorod, as this light is yet little used in Siberia. Besides the building of the houses, the food of the expedition, &c., all will be more difficult to obtain than the same articles wanted by an expedition sailing in ships. The sum of 42,000 roubles has been granted by the Russian Government. The idea of establishing a second station had to be abandoned, the money being barely sufficient for one station. If the Russian Government should give another sum for observations in high latitudes, a station will probably be established at Moller Bay, on the west coast of Novaya Zemlya. This station would be less expensive, there being always a possibility of reaching the place by ship. The expedition starting now takes two sets of meteorological instruments for establishing additional stations at Irkutsk and some point north of it. The chief of the expedition is Lieut. Jurgens, I.R.N.; he is well qualified to fulfil the arduous duties assigned to him. He will be accompanied by Dr. Bruge, medical assistant, and a meteorological assistant.

We direct the attention of our readers to the letter of the Rev. A. E. Eaton in to-day's NATURE, which has so important a bearing on the probable condition of Mr. Leigh Smith's expedition in the *Eira*. From Mr. Eaton's letter it is evident that Mr. Smith deliberately intended to winter at Franz-Josef Land; and to those who know him it is not surprising that he said little about it to his friends. This is also essentially the drift of a short notice on the subject in yesterday's *Times*, where, however, the very inconsequent conclusion is drawn "that a relief vessel should be sent out in the course of next summer by either Mr. Leigh Smith's relatives or the Government." There can be no objection to the relatives sending out an expedition, but so far as present evidence goes, a Government expedition does not seem to be called for.

The news lately received from the Behring Strait whalers discloses a very remarkable condition of things in the Arctic Sea this season. Capt. Williams, of the *Frances Palmer*, reports clear water in N. lat. 73° 30′ to the east of Herald Shoal, and the U.S. Relief-ship *Rodgers* got as far north as 73° 44′ on the west side of Wrangel Land. Other whaling captains assert that this year they went fully two degrees further north than their charts extended, and every one agrees that both the early and latter parts of the season have been open to a degree unparalleled in Arctic records. The Arctic basin has been found to be comparatively shallow, the depth being about twenty three fathoms. The gales which prevailed when the *Thomas Corwin* left the Arctic Sea in the early part of September broke up the ice further north, and the prevalence of northern winds no doubt accumulated it about the north coast of Wrangel Land, and prevented the boats of the *Rodgers* from actually circumnavigating the island. This year's exploring cruise of the U.S. steamer *Thomas Corwin* has been a very remarkable one. The most important event was the landing on, and partial exploration of, Wrangel Land, which Capt. Hooper renamed New Columbia. He discovered there a tolerably large river, which he named the Clarke River, and the course of which a party who landed at its mouth assert that they were able to trace for some forty miles into the interior. The *Thomas Corwin* appears to have had no difficulty in moving to and fro in the Arctic Sea, except early in September, when a second attempt was made to reach Wrangel Land, but failed through fogs and strong gales. Capt. Hooper visited Point Barrow, on the northern coast of Alaska, and found the ice some twenty miles off the shore.

Mr. W. H. Dall, of the U.S. Coast Survey, contributes to the *American Naturalist* for November a paper on the Chukchi and Namollo people of Eastern Siberia, which seems to have been called forth by some criticisms on the part of Lieut. Nordquist in a communication to the St. Petersburg Geographical Society, afterwards reproduced in our Geographical Society's *Proceedings*. If Mr. Dall replies to all his critics, he will next have to take up the subject of the currents of Behring Strait, for the American whaling captains assert that what he has written on this point is incorrect. Capt. Fisher, of the *Legal Tender*, indeed, says that Mr. Dall's observations extended only over a few days, and were made in an eddy current under the lee of the Diomede Islands.

News has been received by the Bremen Geographical Society that two walrus hunters have returned to Tromsö from Spitzbergen, who report that early in September they were fifteen miles north of the Seven Islands (north of Spitzbergen), and that they found the sea quite free from ice in a northerly direction.

On Monday next Mr. Clements R. Markham, C.B., will read a paper before the Geographical Society on the Arctic work of the present year.

Zoologists are indebted to Dr. R. W. Shufeldt, First Lieutenant, Medical Department, U.S. Army, for a highly valuable contribution to the study of the osteology of birds. He has written two essays in the United States Geological and Geographical Survey *Bulletin* of September, 1881—one on the "Osteology of the North American *Tetraonidæ*" (pp. 309–350), and the other entitled "Osteology of *Lanius ludovicianus excubitorides* (pp. 351–359), both illustrated by several plates; and we can only wish that every monographic essay which treats of the anatomical structure of a limited group of birds were written in such a careful and exhaustive manner. There is scarcely a bone which is not correctly figured, most of them life-size, although some might be a trifle more plastic. All of them are treated of separately, and an exact description is given of the general *Tetraonine* feature of the bones, and in instances where the representatives of the genera under notice are aberrant due attention is drawn to the fact. The author frequently refers to allied families, such as the Partridges and others, and throughout the whole paper we see that the work of previous anatomical writers is carefully taken into consideration; and as Dr. Shufeldt had a large series of specimens before him he was enabled to exclude any peculiarities which might have been attributable to malformation of the bones. So far so good; but descriptive anatomy is one thing, and comparative anatomy another. Whenever the author discusses some of the difficult questions of comparative anatomy, as he does more than once, being well aware of the points where there is still a problem to be solved, we are afraid we cannot follow his deductions. One of the figures in the first plate in the paper on the *Tetraonidæ*, and part of the letterpress, is devoted to a demonstration of the "four cranial vertebræ" with all their appendages and derivatives; but although the disarticulated segments are nicely grouped together on the plate, the conclusions he arrives at certainly contain some obvious mistakes. At p. 328, to the ribs generally known as "sterno-costal" the term "hæmal" ribs is applied. Again we are glad to find that the author admits the theory which considers the limbs with their girdles to be transformed and translocated gill-branch elements, but he goes too far. He seems to believe that the scapular arch originally belonged to and constituted the hæmal arches of the occipital vertebræ. Further on we are informed that we may consider the bones of the pelvic girdle to be the pleur- and hæmapophyses of some of the sacral vertebræ—*verbum sat*. We therefore regret that this essay on the *Tetraonidæ*, valuable as it is as a contribution to ornithotomy, should be handicapped by speculations so wild and so dangerous to the credit of comparative anatomy.

In his "Zur Aetiologie der Infectionskrankheiten," A. Weil states the cause of the decay of teeth, whether external or

internal, to be the Schizomycete *Leptothrix buccalis*, the mode of entry and propagation and the life-history of which he follows out in detail. The acids which occur in the mouth, especially lactic acid, while they may greatly promote the decay, cannot give rise to it. The Leptothrix can be readily recognised by its iodine reaction. The author considers further that in many cases diseases of various parts of the body can be distinctly traced to excretions from the mouth and teeth. Other observers had already traced a connection between decayed teeth and septic abscesses, in which was found a fungus similar to that which occurs in decayed teeth.

THE balance has been applied by Herr v. Jolly, at Munich, to the problem of gravitation thus (*Wied. Ann.* No. 10): The instrument was placed in the upper part of a tower, and from each of the scales depended a wire (through a zinc tube) having a second scale at the lower end, 21·005 m. below. These lower scales were 1·02 m. from the ground, so that a lead ball one metre in diameter might be brought under one of them. A body brought from an upper scale into a lower one has an increase of weight corresponding to its degree of approach to the earth's centre and to the increase of acceleration. When the lead ball is brought under the same lower scale its pull is added. The difference of the increments of weight, with and without the lead ball, indicates the amount of pull of the latter, and the quotient of this pull and that of the earth alone furnishes a means (with the law of gravitation) of comparing the density of the earth with that of the lead, and, the latter being known, of determining the mean density of the earth. Referring to the original for details, we merely state that the author finds the mean density 5·692 (probable error not more than ± 0·068). This agrees more or less with other determinations; from the mean of those with the torsion balance it diverges about 2 per cent.

THE death is announced, at the age of eighty-nine years, of Jean Alfred Gautier, the *doyen* of science in Geneva, and one of the most active citizens of that city. M. Gautier belonged to a very old Genevese family, and displayed an early taste for science. In Paris he counted among his teachers such men as Laplace, Lagrange, Legendre, and Poisson, and in England he formed a life-long friendship with Sir John Herschel. When he settled down in Geneva from his travels, he carried on the work of the little observatory then existing at Geneva, and it was through his exertions that a much better one was built, though defective vision did not enable him personally to superintend it. M. Gautier was one of the earliest to discover a relation between sun-spots and terrestrial magnetism, and in many ways he laboured successfully to advance science in his native city.

WE learn also of the death of Dr. Chr. G. A Giebel, Professor in the Philosophical Faculty at Halle University, an eminent zoologist and geologist. He died at Halle on November 14. The death is also announced, on November 11, of Prof. Engelhardt, a well-known Danish antiquarian, and secretary of the Society of Antiquaries at Copenhagen; and of Prof. Paul-Günther Lorentz, a well-known German authority on mosses; he died at Concepcion del Uruguay at the early age of forty-six years.

THE earthquake of November 18 was noticed in Switzerland, shocks being reported from Ragatz and St. Gall. A great area, comprising Westphalia, Hessen-Nassau, and Belgium, was also visited by this phenomenon; it was noticed at Münster, Marburg, Brussels, Tournai, and Liège and Metz. On November 24 at 11 p.m. a shock was observed at Dedenborn, near Montjoie (Rhenish Prussia), and two shocks at Pergine (Southern Tyrol) early on November 20.

IN February next a private scientific exploring tour to Persia will be undertaken by a Viennese medical man, Dr. Polak. He will lead the expedition himself, and will be accompanied by a geologist and a botanist. All expenses will be defrayed by Dr. Polak.

MOST of the members of the Royal Commission on Technical Instruction have returned to England; they have, we understand, accumulated a mass of valuable information in the course of their preliminary tour, which has included the principal centres of industry in France.

THE dinner in commemoration of the Brewster Centenary will take place in Edinburgh to-morrow.

PROF. J. G. MCKENDRICK has been appointed Fullerian Professor of Physiology for three years at the Royal Institution.

THE Vienna Geographical Society will celebrate the twenty-fifth anniversary of its foundation on December 12 and 13 next.

WE have received from the Parkes Museum a copy of the artistic certificate of awards in connection with the International Medical and Sanitary Exhibition, lithographed from the original design by Mr. Cave Thomas. The certificates are now being distributed. The following facts are of interest:—Exhibitors from different parts of the United Kingdom, 414; exhibitors from abroad, 88; making a total of 502 exhibitors, of whom 258 received either awards of the first class, or awards of merit.

A SURVEY party, under Col. Branfil, has left Calcutta for the purpose of verifying and completing the survey of the Megin Archipelago. The work, including the measurement of the base line, is expected to occupy about six months. Dr. Anderson, Superintendent of the Indian Museum, has accompanied the party and will take the opportunity of instituting a thorough investigation of the local fauna.

THE German Government contemplates sending out two expeditions for observing the transit of Venus in 1882: one to the mouth of the La Plata River, the other to Magelhaen's Straits or the Falkland Isles. The expedition of 1874 cost the Government 600,000 marks (30,000*l.*), the one of next year is estimated to cost only 195,000 marks (9750*l.*).

M. MOUCHEZ, director of the Paris Observatory, is making arrangements for taking meteorological observations at an elevation of 2300 metres by means of a captive balloon. The balloon will be charged with ordinary coal-gas. These observations are intended to facilitate the calculation of atmospheric refractions.

DURING November, twenty-two earthquake shocks have been observed in various parts of Switzerland. They seem to have been most numerous in the neighbourhood of Schaffhausen.

A FINE monument has been erected at Bonn on the tomb of the eminent geologist, Prof. Jakob Nöggerath, who died on September 13, 1877. The sculptor is Herr Albert Küpper.

THE preliminary earthworks for the erection of the monument in memory of Justus von Liebig have been begun on the Maximiliansplatz at Munich.

M. TISSANDIER has organised a private company to prosecute his experiments with an electric directing balloon.

SOME of our readers may be glad to know that King's College, London, has a Science Society which meets on Wednesdays at 8 p.m. during term, for the purpose of reading papers on, and for the discussion of, scientific subjects. The papers, we are glad to learn, are generally experimentally illustrated.

DR. TAYLOR, curator of the Ipswich Museum, was on Saturday afternoon presented with a purse of 660*l.*, accompanied with a handsome clock and gold watch for Mrs. Taylor, in recognition of his labours in connection with the museum, and of his annual course of scientific lectures, which for a number of years he has delivered in Ipswich without any emolument. Sir Richard

Wallace presided on the occasion, accompanied by Lady Wallace, and there was a large company present.

A TRAIN of Pullman carriages lighted by electricity has begun to run between London and Brighton.

THE Risikopf, on which the landslip occurred that recently overwhelmed the village of Elm in Switzerland, is being bombarded by heavy artillery in order that all the loose portions may be detached and thus prevent any future catastrophe.

EISENACH is to have an electric railway from the station to the Wartburg Castle, if the Royal permission can be obtained.

THE *British Almanac and Companion* for 1882 contains a summary of Science for 1881 by Mr. J. F. Iselin. It is necessarily meagre, but Mr. Iselin has selected some of the leading points; the geography is pretty full.

THE additions to the Zoological Society's Gardens during the past week include a Black-eared Marmoset (*Hapale penicillata*) from South-East Brazil, presented by Mrs. George Willins; a Tawny Eagle (*Aquila nævioides*) from South Africa, presented by the Hon. — Southey; a Grey-breasted Parrakeet (*Bolborhynchus monachus*) from the Argentine Republic, a Black-headed Conure (*Conurus nanday*) from Paraguay, presented by Mr. J. Lloyd; two Talpacoti Ground Doves (*Chamæpelia talpacoti*) from Para, a Plumbeous Snake (*Oxyrrhopus plumbeus*), two Taraguira Lizards (*Taraguira smithi*), a —— Tree Frog (*Hyla*, sp. inc.) from Brazil, presented by Dr. A. Stradling, C.M.Z.S.; a Red-faced Spider Monkey (*Ateles paniscus*) from Guiana, three Red-billed Tree Ducks (*Dendrocygna autumnalis*) from South America, a Vinaceous Amazon (*Chrysotis vinacea*) from Brazil, a Redshank (*Totanus calidris*), two Dunlins (*Tringa cinclus*), two Razorbills (*Alca torda*), a Grey Plover (*Squatarola helvetica*), a Curlew (*Numenius arquatus*), British, purchased; a Geoffroy's Dove (*Peristera geoffroii*), bred in the Gardens.

THE ROYAL SOCIETY—ADDRESS OF THE PRESIDENT

II.

AFTER the Congress one of the most remarkable events during the present year has undoubtedly been the Electrical Exhibition in Paris. I do not of course purpose to describe it, as many of our Fellows visited it; and full descriptions have reached us through various channels. One point, however, must have struck those who examined any considerable number of the objects; and this I mention, not as in any way disparaging them, but rather as illustrating the stage to which electrical science has attained; namely, that while the assemblage of instruments and appliances was in every way remarkable, and while very great ingenuity and skill had been expended on their contrivance and construction, yet the amount of novelty in the principles involved was comparatively small. Of new combinations, improved methods, and adaptations in detail there was abundance. Some of them even removed former inventions from the category of curiosities to that of instruments for practical employment; or enlarged their sphere of utility from that of the laboratory to that of every-day use. But such is the mass of fruitful matter which science has furnished to the mechanician and constructor, that we might almost wish, from the point of view of the latter, that they may have time to work out more fully than has yet been done, the results of science, before they are called upon to elaborate any fresh materials.

It is now proposed to repeat as far as may be this Exhibition at the Crystal Palace; and the energy with which the proposal has been taken up, and the response with which it has met in many quarters, appear to justify sanguine expectations of its success, at all events from a practical and popular point of view. From the side of science it would doubtless have been far more interesting to look forward to a fresh exhibition, either here or elsewhere, of the progress of electricity after an interval of two or three years. But there is nothing in the present undertaking to interfere with the more advanced project, if, after some such period as that indicated, circumstances should prove favourable. In the mean time it must be remembered that there are very many persons to whom the Paris Exhibition would have proved both interesting and instructive, but who, from one cause or another, were prevented visiting it. Besides this, there are not a few commercial, and even municipal, bodies desirous of adopting some of the modern applications of electricity, but who would be more ready to avail themselves of them after a personal inspection of the instruments and of their mode of action. From this point of view the exhibition may fairly be expected to give considerable impulse to the adoption of electrical appliances in fresh quarters.

But even over and above this practical aspect of the undertaking there may still have been, at the epoch of the Paris Exhibition, some results on the eve of achievement, some remedies for defects, sufficient to transform a doubtful into a certain issue, or even a failure into a success; some steps which may open out new questions, or serve as a departure for new investigations in the subject of electricity. If such should be the case, even science may derive substantial benefit from the proposed undertaking.

But the present year has been rendered generally remarkable, amongst other things, by the multiplicity of its congresses. Apart from those which are concerned with subjects not coming under the head of "Natural Knowledge," there have been held the annual meetings of the British Association, and of the Iron and Steel Institute; the International Medical Congress, in London; the special Congresses on Electricity and on the Transit of Venus, in Paris (mentioned above); that on Geography in Venice; that on Geology in Bologna, and others.

Among all these the International Medical Congress, which this year met in London, stands conspicuous. The work of that meeting showed that the study of medicine by the real workers is, in every part, even the most practical, pursued in a thoroughly scientific spirit; that facts are industriously collected, and patiently grouped and compared; and that conclusions are, if sometimes hastily drawn, yet very cautiously accepted. And there was ample evidence that help, whether in apparatus or in knowledge, is eagerly accepted from all the other sciences, whether their range be far from, or near to, the biological. In short, in the opinion of those best qualified to form a judgment, it is not too much to say that the whole tone of the proceedings of the Congress, though chiefly concerned with practical questions, was, in the best sense, even in the sense which the Royal Society would give to the term, scientific.

Several of the societies meeting annually, or at longer periods, have organisations which, during the intervals between two successive meetings, do useful work. But in all cases the meetings form the most prominent, if not the most important, feature of their life; and, speaking particularly of the meetings themselves, the question has more than once been raised whether they continue to justify the efforts necessary to bring them about. It has been argued that, so many are the scientific periodicals in every civilised country, that all the papers of importance communicated to the meetings would under any circumstances be published in some place or other. Again, it has been urged that, so numerous are the centres of science, so many the means of communication both between places and between persons, that the necessity for these gatherings has, in the natural course of events, become superseded. The time which such meetings and the preparation for them involve, and the trouble which they entail on men already burdened with much work, have also been pleaded on the same side, and objections have been taken on the ground of the useless and irrelevant matter which is too apt to crop up on these occasions. These arguments are certainly not without weight; but there is still another side to the question. It is indeed quite probable that all the more important papers would be published even if the meetings never took place at all. But at these meetings there are usually a number of communications, many, but not all, of local origin, the production of which has been stimulated by the meeting itself; and a fair number of these may be reckoned on the side of gain. Again, it is true that the original idea of a parade or march-past of science, valuable enough when the provinces heard or saw little of science, has become less important now that provincial centres are to be found in almost every large town in the country. Nevertheless, the mere presence of some of the leading men stimulates dormant powers and encourages rising aspirations; and this perhaps all the more the

[1] Address of William Spottiswoode, D.C.L., LL.D., the president, delivered at the anniversary meeting of the Royal Society on Wednesday, November 30, 1881. Continued from p. 119.

case for the very reason that science and scientific names are no longer unknown. That most of the leading men have opportunities of meeting from time to time, and for scientific purposes, is certainly true; but that they should meet also on occasions when science is not too formal, is a thing which has its uses. And a concurrence of minds more numerous and more diversified than usual is sure to be fruitful of results. The whole advantage of these meetings, however, depends ultimately and fundamentally on the presence of a strong scientific element, which, from its own mere dignity and character, will repress all that is unworthy and will leaven the whole lump. Acting on this principle as a scientific duty, many good men have attended these meetings; and although they may have approached them with some degree of reluctance, few who during their attendance have taken their fair share in the proceedings, have come away without having derived a more favourable impression than that with which they entered.

Of such gatherings, the late meeting of the British Association at York was, if I may be permitted to express an opinion, a pattern and exemplar. And although it cannot be expected that in every year there will be so strong a muster as on the occasion of the fiftieth anniversary, yet all well-wishers of the Association must feel that it has entered upon its second half century with vigour and with dignity, and that it now remains only for its future supporters to maintain the high standard with which it has been handed down by those who have gone before.

It may be a matter of regret, although doubtless inevitable, that the same causes which have affected the social, the intellectual, the industrial, and the political life of our generation, and have made them other than what they were, should affect also our scientific life; but, as a matter of fact, if science is pursued more generally and more ardently than in former times, its pursuit is attended with more haste, more bustle, and more display than was wont to be the case. Apart from other reasons, the difficulty, already great and always rapidly increasing, of ascertaining what is new in natural science; the liability at any moment of being anticipated by others, constantly present to the minds of those to whom priority is of serious importance; the desire to achieve something striking, either in principle or in mere illustration; all tend to disturb the even flow of scientific research. And it is perhaps not too much to say that an eagerness to outstrip others rather than to advance knowledge, and a struggle for relative rather than for absolute progress, are among the dangerous tendencies peculiar to the period in which we live. I do not, of course, for one moment mean to imply that this tendency universally prevails, for in Science as well as in other pursuits, I believe that the best of the present would well stand comparison with the best of the past, and that there are nowadays men in the mid-stream of life who are as little affected by the eddies and back-waters with which they are surrounded as were the giants of former days. Nevertheless the danger is a real one, and is to be met with at every turn.

But the part of Cassandra is neither agreeable to the player nor welcome to the audience; nor is it indeed necessary that I should play it; for, even although what I have said be true, it is still, I trust, not the whole truth. I have already spoken of noble exceptions; but although noble exceptions may go far to redeem the character of a nation or of a period, and example may have influences of which we hardly dream, yet for a general remedy I am more inclined to look to the natural course of events, and to what is often loosely spoken of as "things curing themselves." Such a cure may perhaps come about somehow on this wise. So multitudinous are the workers in every science, so numerous are the channels through which their discoveries are chronicled, that it is becoming every year more difficult for even the learned and the well-read to say what is and what is not new, or what has not been published before. Claims for novelty must, therefore, as time goes on, be put forward with greater and greater diffidence. The only originality that can be safely claimed will be originality on the part of the investigator; and the question of absolute priority must be left to the verdict of time and of that sifting process by which ultimately all discoveries will find their proper places in the Temple of Science.

When this stage is reached, and we are even now approaching it, the fever of to-day may in a great measure subside and give place to a more tempered, although still fervent glow of aspiration. The eagerness and haste to which we have become almost accustomed may be chastened by the reflection that questions of priority are not to be settled by a mere stroke of the pen, and that in the comparison of rival claims the question of the quality of work will undoubtedly arise and become interwoven with that of priority. And so in the end it may come to pass that a half understood experiment or a hastily drawn conclusion may avail less than ever for establishing a reputation, and that, even for the purpose of winning the race, it may be worth while to spend sufficient time in laying sure foundations and in building a superstructure commensurate with that on which it stands and well-proportioned in all its parts.

The transference of the Natural History Collections of the British Museum to the new building at South Kensington is still in progress. It is hoped that the building for the specimens preserved in spirits, as well as the fittings for the zoological department, will be so far completed as to allow of the moving of that department during the autumn of 1882. The lighting of the reading-room by Siemens' lamps is so far satisfactory, that it has been decided to keep that room open in future until 8 p.m., instead of 7 p.m. This change, it is hoped, will prove to be of substantial service to a large class of readers.

The Institution founded in 1851, under the title of the Government School of Mines and Metropolitan School of Science applied to Mining and the Arts, for the instruction of students in those branches of science which are indispensable to the Miner, the Metallurgist, the Geologist, and the Industrial Chemist, has this year been organised afresh, and, under its new title of the Normal School of Science and Royal School of Mines, adds to its former functions the training of teachers for the Elementary Science Classes under the Science and Art Department, the multiplication of which, in recent years, is a significant indication of the rapid spread of scientific instruction throughout the country.

The accommodation requisite for practical teaching being inadequate in all cases and totally wanting in respect of many of the classes, in the Museum of Practical Geology in Jermyn Street, and in the Royal College of Chemistry in Oxford Street, all the instruction, except that in Mining, has been transferred to the Science Schools at South Kensington. The staff of professors and lecturers has been increased, and provision has been made for the teaching of various important subjects, such as Mathematics, Drawing, Botany, and the Principles of Agriculture, which were either omitted, or insufficiently represented, in the original programme of the school.

Under its new organisation the Normal School of Science and Royal School of Mines will not merely supply from among its associates persons highly qualified to apply the principles of science to the Mining, Metallurgical, Chemical, and Agricultural industries of the country, and properly trained science teachers; but, through the exhibitions attached to the yearly examinations of the Science and Art Department, it will place within reach of promising young students in all parts of the country, whose means do not enable them to obtain the benefits of a University education, such a training as will enable them to turn their natural abilities to account for the advancement of science and the improvement of its applications to industry. Under the latter point of view, the instruction given in the Normal School of Science will lead up to the special technical training of the Central Institute of the Guilds of the City of London.

Under the auspices of the City and Guilds of London Institute, further progress has been made during the past year in the promotion of Technical Education. It will be remembered that the work at present undertaken by the Institute embraces the establishment of a Technical Science School in Finsbury, a Technical Art School in Kennington, a Central Institution or Higher Technical College in Kensington, the subsidising of existing institutions, affording facilities for Technical Instruction and the encouragement of existing classes in the manufacturing centres by the grants paid to teachers on the results of the Technological Examinations.

In May last the foundation stone of the Finsbury College was laid by H.R.H. Prince Leopold, and the new building, which will afford accommodation for the teaching of applied Chemistry, Physics, and Mechanics, will be finished early in next year. Notwithstanding the inadequacy of the present temporary accommodation, large numbers of students have availed themselves of the instruction afforded. The principles of Electric Lighting, and Transmission of Power, the making of Electrical Instruments, Coal Tar, and Spirit Distilling have been the subjects that have been chiefly studied during the past session.

Since October the classes that were previously conducted by the Artisans' Institute have been transferred to the Finsbury College.

The Institute has under its consideration the establishment of a School for Applied Art in connection with the Finsbury College. Acting on the general principle that every Technical School of this kind ought to provide, in addition to the general course of instruction, as applicable to different industries, special courses applicable to the staple industry of the district, the Council of the Institute are contemplating the establishment of classes in the Finsbury College adapted to the educational requirements of those engaged in Cabinet-making. With this object it will be necessary to attach a School of Design to the College.

The influx of pupils to the studios in Kennington have induced the Council to vote a sum of money for the extension of the building in which the Art School of this district is conducted. These new buildings are nearly completed, and will afford accommodation for Classes in Modelling, Design, and Wood Engraving,

The building of the central institution, which is to be in the first place a school for the training of technical teachers, has been commenced. The first stone was set in July last by H.R.H. the Prince of Wales, who is now the President of the Institute. The plans of this building show accommodation for the teaching of the different branches of Physics in their application to various industries, of Chemistry as applied to trade purposes, and of Mathematics and Mechanics in their application to Engineering. A good engineering school, containing workshops, well supplied with machinery and collections of mechanical instruments and models, such as exist in numerous Continental cities, seems likely to be obtained for London on the completion of this building.

This Institute has done much towards the encouragement of technical instruction in provincial towns, where it is most needed, by its system of annual examinations. In the examination held in May last, 1563 candidates presented themselves, in twenty-eight subjects, from 115 centres, and of these 895 passed. A close connection is being established between the several technical schools which are being now opened in Lancashire and Yorkshire, and the City and Guilds of London Institute. The demands made upon the Institute by Chambers of Commerce in different parts of England satisfactorily indicate the usefulness of this part of the Institute's work.

The programme of Technological Examinations for 1881–82, just issued, shows thirty-two subjects in which examinations may be held, some of which are divided into four or five branches, so that they may be better adapted to individual industries. Whilst attention has in this way been given to the details of different trades, the attempt has been made to secure from candidates passing the Institute's examinations a general knowledge of the principles of their subject and of the relation of closely connected industries with one another.

In order to secure in future efficient teachers, the Council of the Institute have determined after March next not to register as teachers any persons except those who have passed the Institute's Honours Examination, or such as already possess special or distinct qualifications.

The interest which the subject of technical education is beginning to arouse has led to the appointment by the Crown of a Commission to inquire into the education of the industrial classes in England and in other countries; and the City and Guilds of London Institute is represented on this Commission by Prof. Roscoe, who, as President of the Chemical Society, occupies a seat on the Executive Committee, and also by Mr. Philip Magnus, its director and secretary. The Commissioners are at present engaged in making a tour of inspection in France, a section of them having already visited some of the principal technical schools and factories in the north of Italy.

In Meteorological Science the present year has been marked by the publication of an important work ("Die Temperatur Verhältnisse des russischen Reichs," St. Petersburg, 1880), by Prof. Wild of St. Petersburg, on the Temperature of the Russian Empire, embodying, in charts and tables, a great amount of information, hitherto either inaccessible or existing only in scattered memoirs, relating to the meteorology of the vast tracts of Northern Asia. As an interesting particular result it may be mentioned that Prof. Wild has transferred the "Siberian pole of cold in winter" from the neighbourhood of Jakutsk to a point somewhat further north, lying on the Arctic Circle in (about) E. longitude 125°. At this centre of maximum cold, round which the isotherms lie in fairly regular ovals, the mean temperature in January sinks as low as −54° F., the mean temperature at Jakutsk being 11° higher. In close relation to the phenomena exhibited by these charts, Prof. Wild, in St. Petersburg, has been led to study the connection between areas of permanent high or low mean pressure on the one hand, and areas of permanent high or low mean temperature on the other; and he has found this connection to be of the same kind as that known to exist in the case of the shifting areas of high or low pressure, and high or low temperature, which determine the changes of weather. M. Léon Teisserenc de Bort, in Paris, has also investigated the same subject.

The Meteorological Office has completed during the year two works of some interest, which are now ready for immediate publication. The first consists of tables of the Rainfall of the British Isles, prepared at the request of the Council of the Office by Mr. G. J. Symons, F.R.S. These tables include the monthly results recorded at 367 stations in the United Kingdom, being all those for which it was possible to obtain series of observations maintained continuously during the last fifteen years. The second is a volume of charts (with an introduction and explanations) illustrating the meteorology of an ocean district specially important to seamen—that adjacent to the Cape of Good Hope. Some points of novelty are presented by the charts. For example, a new form of "wind-rose," invented by Mr. F. Galton, F.R.S., has been employed, which offers some theoretical advantages over those previously in use, being intended to represent, with geometrical precision, the probability (deduced from the observations) that, in a particular place and at a particular season, a wind blowing between any two given points of the compass will be experienced. Again, for the first time in marine meteorology, the wind observations have been "weighted" with the view of neutralising the tendency to over-estimate the frequency of adverse winds, which has been found to affect meteorological charts injuriously. The work brings into clear relief the most interesting physical feature of the district—one indeed already well known—the intermingling of hot and cold water, brought by the Agulhas and the South Polar currents respectively, and supplies strong evidence for the belief that this intermingling has a large share in producing the atmospheric disturbances so common in the region in which it occurs.

In my Address to the Society in 1879, I stated that an International Conference of a semi-official character had been held, with the view of establishing for one complete year a circle of meteorological observations round the Arctic regions of the globe. Notwithstanding the lamented death of Lieut. Weyprecht, the gallant young discoverer of Franz-Josef Land, by whom the proposal had been originated, it would seem that the efforts of the Conference are likely to be crowned with success. The following stations have already been undertaken by different Governments:—Point Barrow and Lady Franklin's Bay in Smith's Sound, by the United States; West Greenland, by Denmark; Jan Mayen, by Austria; Mossel Bay and Spitzbergen, by Sweden; Bossekop, by Norway; Nova Zembla, by Holland; the Mouths of the Lena, by Russia. The Conference has also been led to hope that the Canadian Government may reinstitute observations at Fort Simpson, and that the Government of France may organise a simultaneous meteorological expedition to Terra del Fuego. It is arranged that the observations should begin as soon as possible after August 1, 1881, and should continue to September 1, 1883.

In astronomy Mr. Gill has completed his discussion of the extensive series of heliometer measures of the parallax of Mars, which he made at Ascension in 1877, and has deduced the value 8″·78 for the solar parallax, corresponding to a mean distance of 93,080,000 miles from the earth to the sun. A value of the solar parallax has also been derived by Mr. D. P. Todd, from the American photographs of the transit of Venus, 1874. The result for the parallax is 8″·883, corresponding to a mean distance of 92,028,000 miles.

A valuable contribution towards the determination of the moon's physical libration has been made by Dr. Hartwig. From a series of forty-two measures made with the Strassburg heliometer he derives values for the physical libration and for the inclination of the moon's axis, substantially confirming the results found by Wichmann, and recently by Prof. Pritchard.

An addition to the small list of stars which have been found to have a measurable parallax has been made by Dr. Ball. He finds that the star Groombridge 1618, which is remarkable for its large proper motion, has a parallax of about one-third of a second, so that it is to be considered one of the sun's nearest neighbours. Dr. Ball has also re-determined the parallax of the

double star 61 Cygni, his result being 0″·468, which agrees more nearly with Struve's value than with Bessel's.

The Cape catalogue of upwards of 12,000 stars is the outcome of Mr. Stone's labours during nine years, as Her Majesty's Astronomer at the Cape, and is the most important catalogue of stars which has yet been formed in the southern hemisphere. Another important contribution to stellar astronomy has been made by Prof. Newcomb, who has recently prepared a catalogue of the places of nearly 1100 standard stars compiled from the best authorities.

In connection with his photometric researches Prof. Pickering has discussed the causes of the variability of stars of short period. Taking the various hypotheses which have been proposed, he finds that for Algol and stars of that type the hypothesis of an eclipsing satellite or cloud of meteors revolving round the star is the only one which satisfies the observed phenomena. In the case of β Lyræ and similar variables the fluctuations of light would be explained as due to rotation round the axis, the two hemispheres being of unequal brightness and the form more or less elongated. Prof. Pickering has very carefully investigated the conditions in each individual case, and has brought together the most important facts bearing on the subject. It may be mentioned that on Prof. Pickering's initiative a committee of American astronomers has been formed to co-operate with European astronomers in selecting a series of stars to serve as standards of stellar magnitude.

The present year has been remarkable for the appearance of two bright comets simultaneously visible to the naked eye. The first comet was first seen in the southern hemisphere before its perihelion passage, and burst upon our view in its full splendour soon after perihelion. The most important point in connection with this comet was that photographs of its spectrum were obtained by several physicists, and in particular by Dr. Huggins, who found on his photographs two strong bright lines in the ultra-violet corresponding to a group in the spectra of compounds of carbon, and also a group of lines between G and h agreeing in position with another carbon band. The photographs also showed a continuous spectrum extending from F to some distance beyond H, on which the dark Fraunhofer lines were seen—an indication that part of the light from comets is reflected solar light.

In the visible portion the continuous spectrum was so bright when the comet was first seen after perihelion that it almost obliterated the ordinary cometary bands. These, however, became afterwards very conspicuous, and five bands were noted which were found to coincide sensibly with the carbon band as given by the flame of the Bunsen burner. On the brightest band, three bright lines corresponding to three lines in the carbon band were seen by several observers at Princeton, U.S. These observations show conclusively that the spectrum of this comet is identical with the first spectrum of carbon, and not with the second.

In the telescope this comet showed striking changes from day to day, and even, according to some observers, from hour to hour, and the head was remarkable for its unsymmetrical appearance. Another point of interest is that the orbit presents a remarkable resemblance to that of the great comet of 1807. As, however, the period of this latter was found by Bessel to be 1540 years, the question arises again, as in the case of the comets of 1843 and 1880, whether there are not two comets travelling along the same path.

The second bright comet was first discovered with the telescope, and gradually increased in brightness till it became visible to the naked eye, though by no means so interesting an object as the preceding comet. Besides these two bright comets, several telescopic comets have been discovered, raising the total for this year to eight. The last but one of these has proved to be a periodic comet, revolving in the short period of about eight years. It was discovered by an Englishman, Mr. Denning, being the first instance of such a discovery in this country for many years.

The Copley Medal has been awarded to Prof. Karl Adolph Wurtz, For. Mem. R.S. Prof. Wurtz has, for many years past, been one of the most distinguished leaders of the progress of chemistry, and is now the most eminent of active French chemists. The younger generation of French chemists were, for the most part, his pupils. His writings have been the medium by which most of the knowledge of the more modern theories of chemistry has been disseminated in France. His discoveries have been fruitful of the greatest results, not merely in the way of enriching the science with a knowledge of many previously unknown compounds and classes of compounds, but more especially in extending and improving our knowledge of the laws of chemical combination.

It was he who first discovered compound ammonias containing alcohol-radicals in the place of hydrogen—a family of compounds which has since acquired enormous development. It was he who first made those remarkable alcohols called glycols, and thus gave the key to the explanation of glycerine, erythrite, mannite, and the sugars. Many other discoveries of his might be quoted; but those who know the influence which these two have exercised on the progress of chemistry can feel no doubt that the author of them is deserving of the highest scientific honour.

One Royal Medal has been awarded to Mr. Francis Maitland Balfour, F.R.S. Mr. F. M. Balfour's investigations in embryology and comparative anatomy have placed him, thus early in life, in the front rank of original workers in these branches of science. His "Monograph upon the Development of Elasmobranch Fishes," published in 1878, embodies the results of several years' labour, by which quite a new light has been thrown upon the development of several important organs in the Vertebrata, and notably of the genito-urinary and nervous systems. More recently Mr. Balfour has published a most important work on "Comparative Embryology" in two large and fully illustrated volumes, which stands alone in biological literature, not only as an admirable and exhaustive summary of the present state of knowledge respecting the development of animals in general, but by reason of the vast amount and the varied character of the original researches which are incorporated in its pages.

A second Royal Medal has been awarded to the Rev. John Hewitt Jellett, F.R.S., Provost of Trinity College, Dublin. Dr. Jellett is the author of various papers on pure and applied mathematics; but the award is more directly connected with his invention of the analyser known by his name, and for the elaborate optico-chemical researches which he has made with it.

This analyser was introduced by its inventor into the instrument by which he has carried on his researches on the state of combination of mixed solutions, as evidenced by the changes in their power of rotating the plane of polarisation consequent upon a change in the proportion of the active ingredients which enter into the solution. This is a problem towards the solution of which ordinary chemical methods can contribute but little. A single instance will suffice to give an idea of the nature of the results. It is known that quinine forms with many acids two series of salts, one having twice the quantity of acid of the other for the same quantity of base, while with other acids only the less acid salt has been obtained; so that the ordinary chemical methods fail to give evidence of the existence of the more acid salt. Now, by examining the rotatory power of a solution of a given quantity of base with different doses of acid, Dr. Jellett was able to obtain evidence of the existence of two, and but two, salts of the base, no matter whether the acid were or were not one which yields two crystallisable salts. A slight deviation in the amount of rotation when the more acid salt began to be formed in tolerable quantity, from what it ought to have been, on the supposition that the whole of the acid introduced was combined with the quinine, was naturally attributed to a slight partition of the acid between the base and the solvent, regarded as a feeble base; but the smallness of the deviation indicated that a solution of the more acid salt mainly existed as such, and that it was not, as some had supposed, decomposed into free acid and the less acid salt.

The Davy Medal has been awarded to Prof. Adolf Baeyer. Prof. Baeyer was already known as the author of many masterly researches in organic chemistry, among which those on uric acid and on metallic acid deserve special mention, before his latest and most remarkable discovery. The process for the artificial formation and manufacture of indigo is the result of long-continued efforts, directed by singularly clear and accurate views of the order and mode of combination of its constituent elements, and of the conditions requisite for obtaining reactions indicated by theory.

The work of the Royal Commission on Accidents in Mines during the past year has been of such great interest, both from a scientific and from a practical point of view, that I venture to note at length some notes upon it, furnished to me by our Fellow, Mr. Warington Smyth, the Chairman.

A preliminary report was presented before the end of the

Session 1881, drawing attention, under the chief heads of the subject, to the facts and opinions elicited from the examination of a large number of competent witnesses.

Experimental inquiries, which will be the subject of a further report, have been instituted for the purposes of testing the various safety-lamps in use, as well as the numerous modifications recently proposed, and of determining the effect of coal-dust in causing or aggravating explosions. From time to time also experiments have been made with a view to substitute, in the breaking down of coal, some other means for the gunpowder shots which have so often, by their flame, caused the ignition of fire-damp.

The presence of a powerful "blower" of natural gas at the Garswood Hall Colliery, near Wigan, with the facilities offered by the proprietors, induced the Commission to erect suitable apparatus for a long series of these trials, and now that it appears desirable to compare the results with what may be obtained in another district and with a differently constituted fire-damp the whole of the apparatus is in course of erection at a colliery in the Rhondda Valley, where a very permanent "blower" offers similar advantages.

In the course of the lamp experiments it came out very clearly, in confirmation of statements before made, that the greatly augmented ventilation in our larger modern collieries has put an end to the fancied security of the simple Davy and Clanny lamps. Their use in fact, unless they be protected by some farther contrivance, is attended with the most imminent risk when the velocity of a current liable to be rendered explosive, exceeds six feet a second. A high degree of importance thus attaches to the comparative trials of lamps in which the flame is sufficiently shielded against the impinging stream of air, and those which have the property when immersed in an explosive mixture, of rapidly quenching both the flame of the wick and of the burning fire-damp.

The terrible disaster which occurred in September, 1880, at the Seaham Colliery, drew more anxious attention than ever to the question of the part played by coal-dust, and a special reference having been made by the Secretary of State for the Home Department to Prof. Abel, C.B., the experiments at Garswood Hall were largely extended. Some of the results were very remarkable; the proportion of fire-damp present with the air may be so small as to elude detection by the ordinary test of the carefully watched flame in the safety-lamp, and yet the presence of dust in suspension will cause rapid ignition, or even explosion, in a degree varying with the proportion of gas and the velocity of the current. Dust was employed from different parts of the works of several collieries where it was suspected that this agent had borne a serious part in intensifying and spreading explosions; and it was found that some of the varieties were far more sensitive than others. Certain kinds of dust, in themselves perfectly non-combustible, were similarly tested, and proved to have an analogous effect in promoting explosion, even when the percentage of gas was exceedingly small.

It is obvious from these facts that under certain conditions it is very important that a satisfactory indicator of minute proportions of fire-damp should be employed; and the further experiments proposed to be carried out by the Commission will include a particular inquiry into this subject.

The question of the feasibility of the introduction of the electric light into the workings of a colliery has been partially solved. The Stanton Coal and Iron Company were induced by the Commission to make a trial of Mr. Swan's lamps in their Pleasley Colliery, near Mansfield. Not only the inset and main road, but some of the "long-wall" faces of work, were brilliantly lighted in this manner. A second experiment of the same kind has been carried out at the Earnoch Colliery, near Hamilton.

The use and abuse of explosives in mining operations have in the last few years formed a subject of much inquiry, especially with reference to the firing of shots in coal-seams liable to be invaded by fire-damp. A return to mere wedging in all cases, as proposed by some officials, would be to ignore the advance of science as well as the necessities caused by competition; and the Commission hopes by further examination, and especially by practical trials, to contribute useful information to the solution of a difficult but important question.

Among the applications of scientific apparatus the employment of the ingenious protected lime-light lamp, and of the portable breathing arrangement of Mr. Fleuss, during the operations for re-opening of parts of the Seaham Colliery, deserves special notice.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Messrs. W. M. Hicks and W. W. R. Ball are appointed Moderators in the Mathematical Tripos for the year beginning next May. The Senior Wranglership will in future be adjudged in June.

The Examiners for the Natural Sciences Tripos in 1882 are Lord Rayleigh, Prof. W. J. Lewis, Prof. Morison Watson (Owens College), Drs. Gaskell, R. D. Roberts, and Vines, Mr. A. G. Vernon Harcourt (Oxford), and Prof A. M. Marshall (Owens College).

Mr. R. T. Glazebrook, Demonstrator of Experimental Physics, is approved as a Teacher of Physics, and Mr. A. S. Lea, Lecturer at Caius College, is approved as a Teacher of Physiology for the purpose of Medical Studies.

Clare College offers a Natural Science Scholarship, examination March 28; subjects: Chemistry, Chemical Physics, Botany, Geology. Candidates must give notice a fortnight previously to the tutor.

GLASGOW.—The matriculations for the present session number 2316, distributed among the various Faculties as follows, viz.:—In Arts 1327, in Medicine 624, in Law 211, in Theology 100, in Arts and Medicine 25, in Arts and Law 9, in Arts and Theology 20. The total number of matriculations last session was 2304, distributed as follows:—In Arts 1406, in Medicine 563, in Law 189, in Theology 85, in Arts and Medicine 29, in Arts and Law 18, in Arts and Theology, 14.

Journal of the Franklin Institute, October.—Experiments on the strength of wrought iron and steel at high temperatures, by Mr. Roelker.—On the proper method of expansion of steam and regulation of the engine, by Prof. Thurston.—On the last experiment with the Perkins machinery of the anthracite, by Ch. Eng. Isherwood.—Radio-dynamic facts, by Dr. Chase.—Universal energy of light, by the same.

Annalen der Physik und Chemie, No. 10.—Photometric researches on absorption of light in isotropic and anisotropic media, by C. Pulfrich.—On the vapour-tension of mixed liquids (continued), by D. Konowalow.—On the heat of formation of water, by A. Schuller.—On the heat-conductivity of gases and its connection with temperature, by L. Graetz.—Past observations on the expansion of water by heat, by P. Volkmann.—On the theoretical determination of vapour-pressure and volumes of vapour and liquid, by R. Clausius.—On heat-conduction in a system of cylinders, and on the experimental determination of the conductivity of water, by H. Lorberg.—On magnetic reaction, by F. Auerbach.—Application of the balance to the problem of gravitation, by Ph. v. Jolly.—On the spectra of hydrogen and acetylene, by A. Wüllner.—Some remarks on Herr Wesendonck's experiments on spectra of carbon compounds, by the same.—The minimum of deflection of a ray of light in a prism, by K. H. Schellbach.—Contribution to history of natural sciences among the Arabians, by E. Wiedemann.

La Natura, Nos. 21 and 22, November.—The Italian section at the Paris Electrical Exhibition, by R. Ferrini.—Thermal radiation of the sun, &c. (continued), by C. Cattaneo.—On the origin of electricity of storm-clouds and of the air, and on electricity in general, by F. G. Nachs.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 17.—"Researches on Chemical Equivalence." By Edmund J. Mills, D.Sc., F.R.S., and J. H. Bicket. Part IV.: Manganous and Nickelous Sulphates.

The authors have examined the precipitability and precipitation of manganous and nickelous sulphates, alone or commixed, by means of sodic carbonate. The chemical events they describe are represented in a series of four hyperbolas, whose equations are given in the memoir. They sum up their results as follows:—(1) Precipitability is a linear function of mass; (2) when the commixed sulphates are precipitated by sodic carbonate, equal weights of them are equally precipitable, the attraction of one of them for the reagent being the inverse of that of the other; (3) when the sulphates are separately precipitated by the same reagent, they are equally precipitable, and do

not exhibit the inverse function; (4) there is some evidence that the precipitabilities of the commixed and separate sulphates are mathematically related in a simple manner; (5) within moderate limits precipitation is not traceably affected by temperature.

"Researches on Chemical Equivalence." By Edmund J. Mills, D.Sc., F.R.S., and Bertram Hunt. Part V.: Nickelous and Cadmic Sulphates.

This series of experiments had for its object the comparison (as in Part IV.) of nickelous sulphate with a sulphate belonging to another group. The precipitability equations for the commixed salts are given; and it is shown that, according to these, nickelous and cadmic sulphates do not admit of comparison as equally precipitable substances. The authors say, in conclusion, "Our present inference with regard to the precipitability of nickelous-cadmic salt will lead (if confirmed by the action of reagents other than sodic carbonate) to the following important criterion:—*Two elements belong to the same group when*, in saline solutions of identical genus, *they may be equally precipitable.*

"Note on the reversal of the Spectrum of Cyanogen," by Professors Liveing and Dewar.

The authors have frequently noticed dark shaded bands which appeared to be the reversals of bands of oxides or chlorides of sundry metals, but only recently have they obtained photographs showing the reversal of the violet and ultra-violet flutings of cyanogen. The most complete reversal of these flutings were obtained by the use of a Siemens' machine in a crucible of magnesia fed with cyanide of titanium. No other cyanide has been found to produce this effect, but borate of ammonia has produced the reversal of the strongest group near L. In one case the reversal was produced by the bright background given by the expanded lines of magnesium when that metal was introduced. Probably the great stability of titanic cyanide and boron nitride has an influence on the result. The difficulty in reproducing the reversal at will is in securing an absorbing stratum of sufficiently high temperature, and at the same time a sufficiently bright background.

Geological Society, November 16.—R. Etheridge, F.R.S., president, in the chair.—Dr. T. Sterry Hunt, who was present as a guest, gave some account of the pre-Cambrian or Eozoic rocks of Europe as compared with those of North America. He had on several occasions studied them, both on the Continent and in the British Isles, especially with Dr. Hicks in Wales in 1878. In North America the recognised base is a highly granitoid gneiss, without observed limestones, which he has called the Ottawa gneiss, overlain, probably unconformably, by the Grenville series of Logan, consisting chiefly of granitoid gneisses, with crystalline limestones and quartzites. These two divisions make up the Laurentian of Canada, and correspond respectively to the Lewisian and the Dimetian of Hicks. Resting in discordance on the Laurentian, we find areas of the Norian or Labrador series (Upper Laurentian of Logan), chiefly made up of anortholite rocks, granitoid or gneissoid in texture, with some true gneisses. The Huronian is seen to rest unconformably on the Laurentian, fragments of which abound in the Huronian conglomerates. To the lower portion of the Huronian the speaker had formerly referred a great series of petrosilex or hälleflinta rocks, described as inchoate gneisses, passing into petrosilex-porphyries, occasionally interstratified with quartzites. This series, in many places wanting both in Europe and America, he is now satisfied forms an underlying unconformable group—the Arvonian of Hicks. Above the Huronian is the great Montalban series, consisting of grey tender gneisses and quartzose-schists, both abounding in muscovite, occasionally with hornblendic rocks. The Pebidian of Hicks includes both the Huronian and the Montalban, to which latter belong, according to the speaker, certain gneisses and mica-schists both in Scotland and in Ireland, as he had many years since pointed out. In some parts of North America he found the Montalban resting unconformably on Laurentian. Above the Montalban comes the Taconian (Lower Taconic of Emmons), a series of quartzites and soft micaceous schists, with dolomites and marbles. All these various series are older than the Lower Cambrian (Menevian) strata of North America; and it may be added that the Keweenian or great copper-bearing series of Lake Superior there occupies a position between the Montalban and the Cambrian. In the Alps the speaker recognises the Laurentian, Huronian, and Montalban, all of which he has lately seen in the Biellese, at the foot of Mont Viso, in Piedmont. The Huronian is the great *pietre verdi* group of the Italians, and much of what has been called altered Trias in this region is, in his opinion, probably Taconian. The Montalban forms the southern slope of Mont St. Gothard, and is the muscovite gneiss and mica-schist of the Saxon Erzgebirge. Here Dr. Credner and his assistants of the Geological Survey have described abundant conglomerates holding pebbles of Laurentian rocks imbedded in the Upper or Montalban gneiss. The pre-Cambrian age of this has been shown by Credner, who has proved by careful survey that the so-called younger or Palæozoic gneisses of Naumann are really but a continuous part of the older series. Late surveys also show that the crystalline rocks of the Taunus are really Eozoic, and not, as formerly maintained, Devonian in age. The speaker insisted upon the fact that where newer strata are in unconformable contact with older ones, the effect of lateral movements of compression, involving the two series, is generally to cause the newer and more yielding strata to dip towards and even beneath the edges of the older rock, a result due to folds, often with inversion, sometimes passing into faults. This phenomenon throws much light on the supposed recency of many crystalline schists.—The following communications were read:—Additional evidence on the land plants from the Pen-y-glog slate-quarry, near Corwen, by Henry Hicks, M.D., F.G.S.—Notes on *Prototaxites* and *Pachytheca* from the Denbighshire grits of Corwen, North Wales, by Principal Dawson, LL.D., F.R.S., F.G.S.

Zoological Society, November 29.—Dr. A. Günther, F.R.S., vice-president, in the chair.—A letter was read from Dr. A. Frenzel announcing his success in breeding parrots of the genus *Eclectus* in his aviary at Freiberg, in Saxony.—A communication was read from Dr. A. B. Meyer, C.M.Z.S, containing the description of a new species of *Eclectus* received from Timorlaut Island, which he proposed to name *Eclectus riedeli*.—Mr. R. Bowdler Sharpe read a note on the genera *Schœnicola* and *Catriscus*, and pointed out that these genera were identical, but that the South-African *S. apicalis* was specifically distinct from the Indian *S. platyura*.—Mr. G. A. Boulenger gave the description of a new species of *Anolis* from Yucatan, proposed to be called *Anolis beckeri*.—Mr. W. A. Forbes gave an account of the observations he had made on the temperature of the Indian Python (*Python molurus*) during her incubation in the Gardens of the Society in June and July last. The result arrived at was that in the present case there was a difference on the whole average of about 1°·4 Fahr. in favour of the female as compared with the non-incubating male when the temperature was taken on the surface, and of more than double that amount when the temperature was taken between the folds of the body.—Dr. Gwyn Jeffreys, F.R.S., F.Z.S., read the fourth of his series of papers on the Mollusca procured during the expeditions in H.M SS. *Lightning* and *Porcupine*, 1869 and 1870. This part concluded the Conchifera or Bivalves. Eighteen additional species, chiefly belonging to the genus *Neæra*, which is peculiar to deep water, were described. The geographical, hydrographical, and geological distribution, as well as the synonymy of all the species named in the paper, were treated of.—A communication was read from Dr. G. Hartlaub, describing the birds collected in Socotra and Southern Arabia by Dr. E. Riebeck. Amongst the Socotran birds was an example of a new species of finch of the genus *Rhynchostruthus*, which he proposed to call, after its discoverer, *R. riebecki*.

Royal Microscopical Society, November 9.—J. W. Stephenson, vice-president, in the chair.—The Rev. J. J. Halley, vice-president of the Microscopical Society of Victoria (one of the affiliated societies), attended the meeting, and gave an account of the progress of biology and microscopy in that colony.—Mr. Stephenson exhibited a slide of *Surirella gemma*, mounted in phosphorus, illustrating in a remarkable manner the advantage of mounting in media of high refractive index. Mr. Crisp, Mr. Crossley, and Mr. Watson exhibited various forms of microscopes and apparatus, and Mr. Mayall an Abbe apertometer of dense glass for measuring apertures up to 1·50 N.A., and a plate ruled by Fasoldt of New York, who claims to be able to rule lines up to 1,000,000 in the inch.—The deaths of M. Nachet, sen., of Paris, and Mr. C. A. Spencer of Geneva, N.Y., were announced.—Two papers were read by Dr. B. Wills Richardson on multiple staining of animal and vegetable tissues, and by Dr. L. G. Mills on diatoms from Peruvian guano; and Mr. T. Charters White exhibited and explained Goodwin's growing slide.—Eight new Fellows were elected.

Anthropological Institute, November 22.—Mr. Hyde Clarke, vice-president, in the chair.—The election of C.

Pfoundes was announced.—Mr. E. B. Tylor, F.R.S., read a paper on the Asiatic relations of Polynesian culture. The author called attention to some new evidence relating to the transmission of civilisation from the Indo-Chinese district of Asia through the Indian Archipelago to Melanesia and Polynesia. The drawings of wooden tombs in Borneo by Mr. Carl Bock show architectural design, apparently derived from the roof-projections of pagodas of Cochin China. The flute played with the nostrils may be traced from India (where it is said to have a ceremonial use to prevent defilement through touching a low-caste mouth), through South-east Asia into Borneo, to the Fiji Islands, and down to New Zealand. Among the traces of mythical ideas having spread from Asia into the South Sea Islands, Mr. Tylor mentioned the notion of seven or ten heavens and hells, apparently derived from the planetary spheres of the Pythagoreans. The Scandinavian myth of the fishing up of the Midgard serpent bears, as Prof. Bastian of Berlin has pointed out, a striking resemblance to Maui's fishing up the Island of New Zealand, and the Maori myth of the separation of heaven and earth has one of its best representatives among the Dayaks of Borneo. Leaving the question of race on one side, it is becoming more and more certain that much of the culture of the Polynesians came in some way from civilised nations of Asia.—The following papers were also read:—On Fijian riddles, by the Rev. Lorimer Fison.—On the stature of the inhabitants of Hungary, by Dr. J. Beddoe.—Notes on the affinity of the Melanesian, Malay, and Polynesian Languages, by the Rev. R. H. Codrington.—The discussion on Mr. Codrington's paper was adjourned to the next meeting, on December 13.

Institution of Civil Engineers, November 22.—Mr. Abernethy, F.R.S.E., president, in the chair.—The paper read was on the "Forces and Strains of Recoil considered with reference to the Elastic Field-Gun Carriage," by Mr. H. J. Butter.

Victoria (Philosophical) Institute, December 5.—The first meeting of the new session was held at the Institute's House, 7, Adelphi Terrace, on Monday evening, when a paper on Mr. Herbert Spencer's "Theory of the Will" was read.

Paris

Academy of Sciences, November 28.—M. Wurtz in the chair.—M. Faye presented the volume of the *Connaissance des Temps* for 1883.—The following papers were read:—New method of annulling the astronomical flexure of telescopes, by M. Villarceau. The simultaneous application to a well-made telescope of two weights in equilibrium, causes a variation of the astronomical flexure, proportional to their difference. Two iron rings, of fixed weight, are applied at distances from the axis of rotation, that are determined by formula.—On the isomeric states of haloid salts, by M. Berthelot.—Summary account of a zoological exploration in the Mediterranean with the Government vessel *Le Travailleur*, by M. Milne-Edwards. This expedition, organised by M. Milne-Edwards, left Rochefort on June 9, and returned August 19. Part of June and all July was devoted to the deeper parts of the Mediterranean. *Inter alia*, many Crustaceans, known only in the Atlantic before, were got in those depths; also remarkable species of Mollusca, Bryozoa, Cœlenterata, &c. The presence of the magnificent sea-star Brisinga was quite unexpected; several specimens were dredged between 550 and 2660 m. No Infusoria, Bacteria, or Microbes were found at great depths; Rhizopods were rare; at 2660 m. some small Actinophrys were obtained. In general the Mediterranean is not to be thought a distinct geological province; its inhabitants have probably come from the ocean, and their development and reproduction have been more active than in their place of origin. Some have been slightly modified. The more we get to know of oceanic productions off the coasts of Portugal, Spain, Morocco, and Senegal, the more do differences from Mediterranean animals disappear.—Fossil man of Lagoa Santa (Brazil), and his present descendants, by M. de Quatrefages. Several human crania were long ago found in a cavern near Lagoa Santa, by Dr. Lund, a Danish *savant*. His letter about them (1844) seems to have been forgotten. Most were sent to Copenhagen, but have not been described. One remaining in Brazil has been studied by Drs. Lacerda and Peixoto, who find the skull to have strong points of similarity to skulls of Botocudos of the present. This M. de Quatrefages confirms, and he further finds the type quite distinct from European fossil man, chiefly in the combinations of dolichocephaly and hypsistenocephaly. This Brazilian fossil man lived in the reindeer epoch. The type (with added ethnic elements not yet determined) is now met with in Ando-Peruvian populations, as well as in Brazil.—Admiral Paris presented a second series of his "Souvenirs de Marine Conservés," plates of old or disappearing types of vessels, comprising Danish ships previous to the siege of Copenhagen, Arab vessels, French fishing-boats, Turkish boats, &c.—Researches on a new property of the nervous system, by M. Brown-Séquard. Various parts of the nervous system may act suddenly, or very rapidly, in a purely dynamic way and without intervention of nutrition, on other parts of this system, so as to increase the power of action of those parts. Thus, *e.g.* by irritation of the skin the excitability of the phrenic nerve of the same side may be at once so increased that the minimum faradic current then required to set the nerve in action may be only one-sixth of that for the same nerve in a similar animal whose cutaneous nerves have not been irritated.—Observation of the new comet (g 1881) at Paris Observatory, by M. Bigourdan.—On algebraic equations of the form

$$\frac{A_0}{x - a_0} + \frac{A_1}{x - a_1} + \ldots + \frac{A_n}{x - a_n} = 0,$$

by M. Laguerre.—Distribution of energy by electricity, by M. Deprez.—Decomposition of vapour of water by electric *effluves*, by MM. Deherain and Maquenne. They show that certain electric discharges without sparks, and at a comparatively weak tension, will decompose water. They used sometimes MM. Thenard and Berthelot's well-known apparatus with double glass envelope, sometimes a tube traversed by a platinum wire, and having some tinfoil outside.—Contribution to the pathological anatomy of the spinal cord in poisoning with phosphorus, by M. Danillo. With phosphorus inflammator-irritation may be produced either in the grey substances alone, or both in that and in the white.—Reply to a note of M. Isambert on carbamate of ammonium, by MM. Engel and Moitessier.—On the post-embryonal development of Diptera, by M. Künckel.—On an electrolytic dosometer for measuring the intensity of the current during medical application of electricity, by M. Pulvermacher. The gases produced by decomposition of water are admitted into a chamber where they act on coloured water, forcing it up a tube to which a graduated scale is attached.—Mr. Axon communicated some facts about articulation by deaf mutes, confirming M. Hément's observations.—M. Bousset reported a curious case of double parturition by a cow.

Vienna

Imperial Institute of Geology, Nov. 22.—The following papers were read:—R. Hoernes, contributions to the knowledge of mid-Meiocene Trionyx species in Styria.—Standfest, on the Devonian formation in the environs of Gratz.—F. Kreutz, contributions to the explanation of the ozokerite and naphtha occurrence in Gallicia.—T. Woldrich, contributions to the knowledge of the fauna of Moravian caves.—E. Reyer, on the eruptive rocks of Toscana and Elba.

CHARLES LYELL

Life, Letters, and Journals of Sir Charles Lyell, Bart., Author of the Principles of Geology, &c. Edited by his Sister-in-law, Mrs. Lyell. In two volumes. With Portrait. (London: John Murray, Albemarle Street, 1881.)

I.

"THE Principles of Geology" and "The Origin of Species" are the two books which have unquestionably exercised the most powerful influence upon the direction of scientific thought during the present century. The first of these works not only prepared the way for the second, but, as Darwin himself has told us, may actually be regarded as its progenitor, for it was the study of the "Principles" which induced the young naturalist to make his now famous "Voyage Round the World" and to collect those facts and observations out of which eventually grew the theory of Natural Selection. The wonderful revolution in thought which followed the appearance of the "Origin of Species" is still fresh in our minds, but those who could remember the effects produced by the publication of "The Principles of Geology," were wont to relate that fifty years ago scientific thought and speculation received an impetus no less powerful than that of which we have witnessed the results in our own time.

The story of the life of Sir Charles Lyell is the history of "The Principles of Geology," for all Lyell's other scientific writings are either expansions of portions of that great work, or are in some way or other supplementary to it. In the account of Lyell's earlier years we trace the birth and development of the ideas so clearly embodied in this famous book, while by the records of his later years we are reminded of the untiring energy with which he collected materials to expand and illustrate those ideas in the successive editions of the work.

The volumes before us enable us for the first time to trace this interesting story in all its details, and we cannot speak too highly of the skill and judgment with which the editor has arranged the materials at her command. The book consists essentially of Lyell's own journals and letters, a few short explanatory notes on the chief events of his life being interspersed in small type and inserted between brackets, together with a few foot-notes explaining allusions or giving details about persons mentioned in the letters.

Lyell, though born in Scotland, was by descent and education an Englishman. His earlier years were spent either in the New Forest and the towns in the south of England, where he went to school, or at the home at Kinnordy, in Forfarshire, where the family usually spent the autumn. In the south of England young Lyell, whose attention had been from boyhood directed to entomology, had the opportunity of studying the Tertiary deposits of the Hampshire basin; while in Forfarshire the draining of a small loch on his father's property and the excavation of the "marl" with which it had become filled, appear to have early directed his attention to some of the important questions connected with the mode of deposition of strata and the way in which organic remains become imbedded in them—questions afterwards treated by him with such skill and ingenuity in the "Principles." Lyell's two first papers, published in the *Transactions* of the Geological Society, relate to the strata of the Hampshire Basin and the formation of these marl-deposits in the lakes of Forfarshire.

At the age of seventeen Lyell went to Oxford, and there came under the influence of the brilliant and versatile, but eccentric, Buckland. But though impressed with the eloquence and filled with admiration at the energy of his teacher, there is evidence that at a very early date Lyell's mind underwent a revolt against the bold but shallow theorisings of the Oxford professor. When a few years later Buckland published his "Reliquiæ Diluvianæ," we find the pupil not only in open opposition to the master, but actually leading the attacks of the "Fluvialists" against the great stronghold of the "Diluvialists."

Upon leaving Oxford, Lyell was destined for the bar, but he, after reading law for a short time, was obliged to desist on account of the weakness of his eyesight. Under these circumstances he repaired to Paris, where he had the opportunity of constant intercourse with Cuvier, Brongniart, Humboldt, Constant Prévost, and the other brilliant scientific thinkers who were at that period assembled in the French capital. He at the same time studied with care the Tertiaries of the Paris basin, comparing the strata and their fossils with those with which he was already so familiar in Hampshire.

Lyell had now become so thoroughly engrossed in scientific work that all idea of advancement at the bar was abandoned by him, and after going two years upon the Western Circuit, he seems to have finally relinquished law for literature and science. He first began to write in the *Quarterly Review*, having formed a close friendship with Lockhart, then editor of that journal, and, after some papers upon educational questions, he in 1827 undertook a review of Scrope's "Geology and Extinct Volcanoes of Central France." It was in this work that Lyell first showed how entirely he had adopted the principles enunciated by Hutton and Playfair, and how far he was in advance of his most eminent contemporaries, Buckland and Sedgwick in England, and Cuvier and Humboldt on the Continent.

The five years from 1825 to 1830, during which Lyell was maturing his literary style by writing for the reviews and collecting the materials for his great work, may be regarded as the turning-point of his career, and the letters written by him at this period are of the greatest interest to the historians of science. We cannot forbear from making a few extracts illustrating the nature of his work and his views at this period. On June 22, 1826, he wrote to his friend Dr. Mantell—

"I must not sport radical, as I am become a Quarterly Reviewer. You will see my article just out on 'Scientific Institutions,' by which some of my friends here think I have carried the strong works of the enemy by storm. I am now far on with a second, and hope to get it out in less than three months. I mean to help myself out of Cuvier largely, for I must write what *will be read*" (vol. p. 164).

On March 2, 1827, he writes to the same correspondent as follows:—

H

"I devoured Lamarck *en voyage*, as you did Sismondi, and with equal pleasure. His theories delighted me more than any novel I ever read, and much in the same way, for they address themselves to the imagination, at least of geologists who know the mighty inferences which would be deducible were they established by observations. But though I admire even his flights, and feel none of the *odium theologicum* which some modern writers in this country have visited him with, I confess I read him rather as I hear an advocate on the wrong side, to know what can be made of the case in good hands. I am glad that he has been courageous enough and logical enough to admit that his argument, if pushed as far as it must go, if worth anything, would prove that man may have come from the Ourang-Outang. But after all, what changes species may really undergo! How impossible will it be to distinguish and lay down a line, beyond which some of the so-called extinct species have never passed into recent ones. That the earth is quite as old as he supposes, has long been my creed, and I will try before six months are over to convert the readers of the *Quarterly* to that heterodox opinion" (vol. i. p. 168).

His aspirations concerning his future at that time will be understood from the following extract from a letter written to his father in the same year :—

"I find my wants diminish monthly in proportion as I am more agreeably employed, and if with the willingness to work and industry which I now have, I had any chance of earning what I require by my own exertions, I should be without a care as far as I am myself concerned. But to be willing without avail to work hard, and almost for nothing, is now the fate of many hundreds of barristers, and many millions of our labouring classes, and we must congratulate ourselves at not being among the latter. I am quite clear, from all that I have yet seen of the world, that there is most real independence in that class of society who, possessing moderate means, are engaged in literary and scientific hobbies; and that in ascending from them upwards, the feeling of independence decreases pretty nearly in the same ratio as the fortunes increase. My eyes go on tolerably, and I feel my facility of composition increases, and hope to make friends among those that a literary reputation will procure me who may assist me" (vol. i. p. 171).

Under date of February 5, 1828, he wrote to Dr. Mantell explaining his plans for the work which he had been for some time contemplating :—

"I at first intended to write 'Conversations on Geology"; it is what no doubt the booksellers, and therefore the greatest number of readers, are desirous of. My reason for abandoning this form was simply this; that I found I should not do it at all, without taking more pains than such a form would do justice to. Besides, I felt that in a subject where so much is to be reformed and struck out anew, and where one obtains new ideas and theories in the progress of one's task, where you have to controvert, and to invent an argumentation—work is required, and one like the 'Conversations on Chemistry' and others would not do. It should hardly be between the teacher and the scholar perhaps, but a dialogue like Berkeley's Alciphron, between equals. But finally I thought that when I had made up my own mind and opinions in producing another kind of book, I might then construct conversations from it. In the meantime there is a cry among the publishers for an elementary work, and I much wish you would supply it. Anything from you would be useful, for what they have now is positively bad, for such is Jamieson's 'Cuvier'" (vol. i. p. 177).

In attempting to free geological science from the trammels with which it had become involved by the efforts of well-intentioned but mischievous works, like the "Vindiciæ Geologicæ" and the "Reliquiæ Diluvianæ," Lyell undertook no light or easy task. His letters to Scrope, who had been requested by Lockhart to review the "Principles" in the pages of the *Quarterly*, show very clearly how sensible Lyell was of the difficulties by which he was beset through the nervous susceptibilities of orthodoxy. The fact that the works of Hutton and Playfair had long ago been placed in a social "Index Expurgatorius," and that Scrope's clear and admirable exposition of the Huttonian doctrines, published in his "Considerations on Volcanoes" in 1825, had altogether failed to revive interest in the ostracised works, was full of warning to Lyell. We find him writing to Scrope, while the first volume of the "Principles" was going through the press, in the following terms :—

"I was afraid to point the moral, as much as you can do in the *Q. R.*, about Moses. Perhaps I should have been tenderer about the Koran. Don't meddle much with that, if at all.

"If we don't irritate, which I fear that we may (though mere history), we shall carry all with us. If you don't triumph over them, but compliment the liberality and candour of the present age, the bishops and enlightened saints will join us in despising both the ancient and modern physico-theologians. It is just the time to strike, so rejoice that, sinner as you are, the *Q. R.* is open to you.

"If I have said more than some will like, yet I give you my word that full *half* of my history and comments was cut out, and even many facts; because either I, or Stokes, or Broderip felt that it was anticipating twenty or thirty years of the march of honest feeling to declare it undisguisedly. Nor did I dare come down to modern offenders. They themselves will be ashamed of seeing how they will look by-and-by in the pages of history, if they ever get into it, which I doubt. You see that what between Steno, Hooke, Woodward, De Luc, and others, the modern deluge systems are all borrowed. Point out to the general reader that my floods, earthquakes, &c., are all very modern, also waste of cliffs; and that I request that people will multiply, by whatever time they think man has been on the earth, the sum of this modern observed change, and not form an opinion from what history has recorded. Fifty years from this, they will furnish facts for a better volume than mine. . . ."

"I conceived the idea five or six years ago, that if ever the Mosaic geology could be set down without giving offence, it would be in an historical sketch, and you must abstract mine, in order to have as little to say as possible yourself. Let them feel it, and point the moral" (vol. i. p. 271).

On two points, as has often been pointed out, Lyell may be held to have betrayed weakness in his reasoning in the "Principles." The first of these was that he appeared to accept in the most uncompromising manner the stringent Uniformitarian views of Hutton, leaving no place even for variations in the intensity of causes now operating. In taking this line he was doubtless influenced by fear of making any dangerous concessions to his adversaries the "Diluvialists." His real feelings on the subject may be gathered from a letter in which he replies to the remonstrances of Scrope upon the subject—

"All I ask is, that at any given period of the past don't stop inquiry when puzzled by refuge to a 'beginning,' which is all one with 'another state of nature' as it appears to me. But there is no harm in your attacking me, provided you point out that it is the proof I deny, not the probability of a beginning. Mark, too, my argument,

that we are called upon to say in each case, 'Which is now most probable, my ignorance of all possible effects of existing causes,' or that 'the beginning' is the cause of this puzzling phenomenon?" "It is not the beginning I look for but proofs of a *progressive* state of existence in the globe, the probability of which is *proved* by the analogy of changes in organic life" (vol. i. p. 270). See also upon the same subject his letter to Whewell in 1837 (vol. ii. p. 2).

The other question upon which Lyell's reasonings in his "Principles" betrayed weakness and inconsistency was that of the cause of the appearance from time to time of new species of plants and animals upon the earth. While stoutly maintaining the sufficiency of existing causes to account for the gradual disappearance of species by extinction, he felt himself compelled to invoke a creative power to introduce the new species as they were required. But, before we blame Lyell for this apparent weakness, we ought to remember that the work of Lamarck, the only serious attempt which had been at that time made to account for the origin of species, though brilliant and suggestive, was full of assumptions and fallacies that could not fail to betray themselves to Lyell's logical mind, and to militate against his acceptance of the theory. Lyell, moreover, saw only too clearly that the origin of man could not be treated of on different principles to that of other species of animals, and to have come into conflict with the prejudices of the day upon such a point as this, would have been to sacrifice all chance of a patient hearing for his arguments in favour of the "good cause" of which he felt himself to be the apostle. A very interesting letter written by him to Sir John Herschel in 1836, shows very clearly that Lyell had even at that early date thought deeply on the question of the origin of species by natural causes.

"In regard to the origination of new species, I am very glad to find that you think it probable that it may be carried on through the intervention of intermediate causes. I left this rather to be inferred, not thinking it worth while to offend a certain class of persons by embodying in words what would only be a speculation. But the German critics have attacked me vigorously, saying that by the impugning of the doctrine of spontaneous generation, and substituting nothing in its place, I have left them nothing but the direct and miraculous intervention of the First Cause, as often as a new species is introduced and hence I have overthrown my own doctrine of revolutions, carried on by a regular system of secondary causes. I have not wasted time in any controversies with them or others, except so far as modifying in new editions some opinions or expressions, and fortifying others, and by this means I have spared a great deal of ink-shed, and have upon the whole been very fairly treated by the critics. When I first came to the notion, which I never saw expressed elsewhere, though I have no doubt it had all been thought out before, of a succession of extinction of species, and creation of new ones, going on perpetually now, and through an indefinite period of the past, and to continue for ages to come, all in accommodation to the changes which must continue in the inanimate and habitable earth, the idea struck me as the grandest which I had ever conceived, so far as regards the attributes of the Presiding Mind. For one can in imagination summon before us a small part at least of the circumstances that must be contemplated and foreknown, before it can be decided what powers and qualities a new species must have in order to enable it to endure for a given time, and to play its part in due relation to all other beings destined to coexist with it, before it dies out. It might be necessary, perhaps, to be able to know the number by which each species would be represented in a given region 10,000 years hence, as much as for Babbage to find what would be the place of every wheel in his new calculating machine at each movement.

"It may be seen that unless some slight additional precaution be taken, the species about to be born would at a certain era be reduced to too low a number. There may be a thousand modes of insuring its duration beyond that time; one, for example, may be the rendering it more prolific, but this would perhaps make it press too hard upon other species at other times. Now it it be an insect it may be made in some of its transformations to resemble a dead stick, or a leaf, or a lichen, or a stone, so as to be somewhat less easily found by its enemies; or if this would make it too strong, an occasional variety of the species may have this advantage conferred upon it; or if this would be still too much, one sex of a certain variety. Probably there is scarcely a dash of colour on the wing or body of which the choice would be quite arbitrary, or which might not affect its duration for thousands of years. I have been told that the leaf-like expansion of the abdomen and thighs of a certain Brazilian Mantis turn from green to yellow as autumn advances, together with the leaves of the plants among which it seeks for its prey. Now if species come in in succession, such contrivances must sometimes be made, and such relations predetermined between species, as the Mantis, for example, and plants not then existing, but which it was foreseen would exist together with some particular climate at a given time. But I cannot do justice to this train of speculation in a letter, and will only say that it seems to me to offer a more beautiful subject for reasoning and reflecting on, than the notion of great batches of new species all coming in, and afterwards going out at once" (vol. i. pp. 467, 469).

It is probable that during later years Lyell receded somewhat from the position he was prepared to take up at the time when he wrote the above. The crudeness of speculation and ignorance of scientific facts which characterised the earlier editions of the "Vestiges of Creation" had in all likelihood not a little to do with this revulsion of thought, while the powerful influence of the leaders of biological thought, Edward Forbes and Louis Agassiz, always exercised in support of the idea of the permanency of species, doubtless had no little weight with Lyell, as it had with nearly all his contemporaries. How readily Lyell welcomed and embraced the views of Darwin as soon as they were published we all know, for he could not fail to see that by incorporation of the theory of natural selection into his work he was for the first time able to make it complete and consistent with itself. It is interesting to read in the volume before us the impressions made upon him by the first reading of the "Origin of Species" in 1859.

"My dear Darwin,—I have just finished your volume, and right glad I am that I did my best with Hooker to persuade you to publish it without waiting for a time which probably could never have arrived, though you lived to the age of a hundred, when you had prepared all your facts on which you ground so many grand generalisations.

"It is a splendid case of close reasoning and long-sustained argument throughout so many pages, the condensation immense, too great perhaps for the uninitiated, but an effective and important preliminary statement, which will admit, even before your detailed proofs appear, of some occasional useful exemplifications, such as your pigeons and cirripedes, of which you make such excellent use.

"I mean that when, as I fully expect, a new edition is soon called for, you may here and there insert an actual case, to relieve the vast number of abstract propositions. So far as I am concerned, I am so well prepared to take your statements of facts for granted, that I do not think the *pièces justificatives* when published will make much difference, and I have long seen most clearly that if any concession is made, all that you claim in your concluding pages will follow.

"It is this which has made me so long hesitate, always feeling that the case of Man and his Races and of other animals, and that of plants, is one and the same, and that if a *vera causa* be admitted for one instant, of a purely unknown and imaginary one, such as the word 'creation,' all the consequences must follow" (vol. ii. p. 325.

After the first publication of the "Principles" between the years 1830 and 1833, a great part of Lyell's time and thought was given up to revising, enlarging, and re-writing portions of his book during the twelve editions through which it passed. Although many valuable corrections were made in the original work, its scope and arguments being extended, and the whole fortified with a great wealth of new illustrations, it may well be doubted whether this continual re-editing of the book was not attended with some loss in the symmetry of its arrangement and its literary excellence. In a work relating to such a rapidly-advancing science as geology, this result, much as it is to be regretted, could scarcely be avoided; but many disciples of Lyell, while they refer to the last edition as a store-house of facts, will delight to renew their acquaintance with an old favourite by reading once more the easily flowing periods of the first edition.

We have dwelt at such length upon Lyell's relations to his great work, as illustrated in the interesting volumes before us, that we must defer to a second notice some of the other interesting topics which are suggested by their perusal.

JOHN W. JUDD

ORGANIC CHEMISTRY

Adolph Strecker's Short Text-book of Organic Chemistry. By Dr. Johannes Wislicenus, Professor of Chemistry in the University of Würzburg. Translated and edited by W. R. Hodgkinson and A. J. Greenaway. 8vo. (London: Kegan Paul, Trench and Co., 1881.)

THE new edition of Strecker's text-book by Prof. Wislicenus, published in 1874, is well known as giving a concise and comprehensive view of the state of organic chemistry at the time of its publication, and some useful additions, relating to recent discoveries, have been made by the English translators.

The classification of organic compounds in this, as in all recent works on organic chemistry, is based upon the hydrocarbons. All organic compounds of known constitution are divided into the two great groups, Fatty and Aromatic, and in each of these the saturated hydrocarbons—paraffins in the first, benzene and its homologues in the second,—are first described; next their mono-substitution derivatives: alcohols, ethers, amines, phosphines, &c.; then in succession the di-, tri-, tetra-, &c., derivatives. With regard to this matter Prof. Wislicenus says in his preface: "The most systematic arrangement would be found in the number of carbon-atoms in direct union. In each such group of equal carbon contents the paraffin would come first, next those derivatives in which only a single hydrogen-atom had been replaced, these being arranged according to the valency of the substituting element. Then would follow the di-substitution products. . . Next the tri-substituted paraffins. . . . This order of arrangement is very valuable for the study of organic chemistry, more so however for those moderately acquainted with the subject than for beginners. For the latter I think we cannot dispense with the study of homologous series, especially in the early part of a text-book. In this way alone can the clear differentiation of the various categories be made evident, depending, as they do, not so much on the accumulation of carbon-atoms, as on the nature and amount of the other elements in union." It is worth while to compare these remarks with those made by Roscoe and Schorlemmer in their lately-published "Treatise on Organic Chemistry," at p. 129 of which we read:—"Perhaps the most systematic mode of arrangement would be to commence each group (fatty and aromatic) with a discussion of the hydrocarbons, and then to follow on with a description of the series of substances obtained by the replacement of one, two, three, or more of the constituent atoms of hydrogen. Such a mode of classification, however, labours under the disadvantage that compounds which stand as a rule closely together, as, for example, the alcohols $CnH_{2n+2}O$ and the acids $C_nH_{2n}O_2$, are thus found widely separated, whilst other groups possessing but little analogy are brought into proximity. Hence it is desirable, alike for the sake of perspicuity as for the purpose of showing the genetic relationships between different bodies, to depart in many cases from such a systematic treatment, and arrange the compounds according as they are derived one from the other." It will be seen from these quotations that each author regards the arrangement adopted by the other as the most systematic, but prefers his own as best adapted to the requirements of the student.

The additions made to the work under consideration by the English editors belong chiefly to the aromatic group, but no mention is made of the recent investigations of Nevile and Winther, published last year in the Journal of the Chemical Society, on the Bromotoluenes, which are especially interesting on account of the light which they throw on the influence exerted by the groups or radicles which have replaced certain hydrogen-atoms in a benzene nucleus, on the position taken up by other radicles which take the place of the remaining atoms of hydrogen. In the series of paraffins there is an omission of the normal Heptane, lately discovered by Dr. Thorpe in the turpentine of *Pinus Sabiniana;* and amongst the nitroparaffins no notice is taken of the Nitrolic acids and Pseudonitroles. Under the organic compounds of boron we miss Dr. Frankland's Ammonioboric methide, $(CH_3)_3B{=}NH_3$ and Diboric ethopentethylate, $(C_2H_5O)_3B{=}B(C_2H_5)(OC_2H_5)_3$, in which boron figures as a pentad; and under guanidine there is no account of the Guanamines, $C_{n+2}H_{2n+3}N_5$, a series of bases discovered by Nencki in 1874 and 1876, and formed by the action of heat on the guanidine salts of the fatty acids.

The translation reads well, and, with the exception of a few instances of somewhat too close imitation of German forms, is expressed in good idiomatic English. There

are, however, certain irregularities of nomenclature which it may be worth while to notice, partly with the view to correction in future editions, partly because the greater number of them are not peculiar to this work, but are of very frequent occurrence in our chemical literature.

On p. 91 we read: "Carbon monoxide is the common radical of the carbonic acid derivatives, and as such is termed 'carboxyl'"; on the next page the compound CONH is called "carboxylimide"; and on p. 98 we read, "corresponding to carbo*x*yl is the radical CS, thiocarbo*n*yl." Here (and in the original) there is surely an inconsistency; if CS is thiocarbonyl, CO should certainly be called carbonyl; and such in fact is the name hitherto given to it by all writers, whereas carboxyl always denotes the group COOH. By a similar inconsistency the term *Ethyl-carbonic acid* is used on p. 353 as a synonym of propionic acid. Now most readers would probably understand by this term the compound $CO(OC_2H_5)(OH)$, *i.e.* carbonic acid having one of its hydrogen-atoms replaced by ethyl—an acid of which several salts are known—whereas propionic acid is $C_2H_5.COOH$, and its proper synonym is *ethyl-carboxylic acid.* The mistake here made arises from a too close imitation in sound of the German term "Carbonsäure," which, with the prefixes mono-, di-, tri-, was introduced by Kolbe to denote the number of carboxyl-groups, COOH, contained in an organic acid. In many instances however this term is correctly rendered; thus on pp. 557 and 561 we find the acids $C_6H_4(COOH)_2$ spoken of as *benzene-dicarboxylic acids*, though further on (p. 653) the same acids are called *phenylene-dicarbonic acids.* It seems indeed as if the two terminations were used indiscriminately.

Another irregularity of frequent occurrence in English nomenclature is the indiscriminate use of the terminations *in* and *ine.* Dr. Hofmann suggested some years ago that *ine* should be used exclusively for organic bases, and *in* for neutral bodies, such as glucosides, bitter principles, proteids, &c. This rule has been followed by some authors, and the writer of this review has taken some pains to recommend its general adoption; but the two terminations are still, by many writers, used without discrimination. As examples of this in the volume under consideration may be cited, on the one hand, gelatine, cholesterine, and on the other, chondrin, albumin, fibrin, dyslysin, &c. Now the use of special terminations for each group of compounds is very much to be desired; it is by no means an innovation, but, on the contrary, is as old as our systematic nomenclature itself; witness the well-known rule that the names of acids shall end in *ic* and *ous*, and those of the corresponding salts in *ate* and *ite.* To extend this regularity of termination to the names of all classes of compounds, especially in organic chemistry, is a main object of the rules lately issued by the Council of the Chemical Society to the Abstractors for that Society's journal, and its general adoption would certainly lead to a great improvement in our nomenclature in point of regularity.

The habit already noticed of too closely imitating foreign forms sometimes leads to awkwardness of expression in translating, as on p. 103, where it is said that "the paraffins burn easily when heated in an *oxygen-containing* atmosphere" (*in einer sauerstoffhaltenden Atmosphäre*); now it would have been quite as easy, and more in accordance with English usage, to say "in an atmosphere containing oxygen." Similar remarks may be made respecting the expression "carbon-free radical," which occurs on p. 565. It is worth some trouble to keep our language pure, and there is no more fruitful source of corruption in a language than the careless imitation of foreign words and idioms. And here I cannot avoid entering a protest against the use, in English speaking and writing, of the French words *mètre*, *décimètre*, &c., instead of their English equivalents, meter, decimeter, &c. *Meter* is a true English word, and is used both singly and in combination, as in the words barometer, thermometer, gasometer, &c., and there is therefore not the slightest occasion for interlarding our sentences with the French forms in question.

The translation affords also some instances of a very common error, viz. a confusion between the terms *substitution* and *replacement.* These words are indeed commonly regarded as synonymous, whereas they are really correlative, and the relation between them is this: *When* A *comes in and* B *goes out*, A *is substituted for* B, *and* B *is replaced, or displaced, by* A. The common error is to say "substituted," where the proper term would be "replaced." Examples both of the correct and incorrect use of these words may be found on pp. 100 and 101, *e.g.* "The hydrogen-atoms of the paraffins can be replaced . . . . by the halogen-atoms," &c.: this is correct; but a little lower down we find, "By *substitution* of only a single hydrogen-atom . . . ."; it should be by *replacement.* The same mistake occurs on the last line of p. 100; on the other hand the word "replaced" is correctly used in several places on p. 102. It would seem, therefore, that the translators regard the two words in question as synonymous.

Next with regard to notation: Many of the graphic formulæ throughout the volume are unnecessarily drawn out into long vertical columns, where they might with equal clearness have been printed horizontally; in one instance indeed seven formulæ fill up a whole page. In this, however, the English editors have simply followed the practice of the original work; but this was printed in 1874, and since that time it has been found that chemical formulæ may for the most part be printed much more concisely without any sacrifice of clearness. The formula of arsenic trichlorodimethide, for example, which is printed in the form $As\begin{cases}CH_3\\CH_3\\Cl\\Cl\\Cl\end{cases}$, might perhaps have been condensed into $(CH_3)_2AsCl_3$, without doing any great violence to the views of the author.

A more important matter, however, relating to notation is the habitual omission—sanctioned indeed by prevailing usage—of brackets in formulæ, where they ought to be inserted. It is of course unnecessary to insist upon the difference between $2a + b$ and $2(a + b)$, with which every schoolboy becomes familiar at a very early stage of his mathematical studies; but unfortunately it has lately become the fashion to ignore this difference in chemical formulæ, and to represent, for example, two molecules of alcohol by $2C_2H_5.OH$ instead of the proper form, $2(C_2H_5.OH)$. Now the neglect of this difference is of

quite recent introduction; for in chemical books of older date it was always observed, in proof of which see Gmelin's "Handbuch der Chemie" throughout. Gmelin indeed, in the first volume of his great work (4te Auflage, 1843, p. 61, and English Edition, i. 61) lays down the law of the case as follows:—"A number placed before several symbols multiplies them all, *as far as the next* + *sign or comma;* or if it stands before a bracket, it multiplies all the symbols and numbers included within the brackets." This rule is consistently followed all through the "Handbuch," and, so far as I know, in most contemporary chemical writings; but lately it has fallen into disuse, and a numeral placed before a set of unbracketted symbols is supposed to multiply them all, whether separated by addition-signs (+ , .) or not. Now this last practice would be all very well if consistently followed out; but unfortunately it is not, and hence confusion arises. For example, the formula $2SO_3, H_2O$ is used, sometimes to signify $S_2O_7H_2$, that is to say, one molecule of pyrosulphuric acid, while at other times it is employed to denote $S_2H_8O_4$ or $2SO_4H_2$, *i.e.* two molecules of sulphuric acid, which latter, according to earlier usage, would have been represented by $2(SO_3, H_2O)$. Again, in the formulæ of basic salts we find such expressions as $3Fe_2O_3, SO_3$, and $2Fe_2O_3, 3SO_3$, &c., in which the co-efficient 3 or 2 is understood to multiply only the Fe_2O_3, without affecting the SO_3; these formulæ being in fact identical with $SO_3, 3Fe_2O_3$ and $3SO_3, 2Fe_2O_3$ respectively. Now it is easy to see that this varying practice in the use or omission of brackets must lead to confusion, and it is much to be desired that the rule which formerly prevailed should be restored to use.

In conclusion, I hope it will be understood that the preceding criticisms are offered solely with the view of promoting uniformity in our nomenclature and notation, and by no means in disparagement of the volume under review, which is in every way a useful and valuable addition to English chemical literature. H. WATTS

OUR BOOK SHELF

Inorganic Chemistry, Theoretical and Practical. An Elementary Text-Book. By William Jago, F.C.S., &c. (London: Longmans, Green, and Co., 1881.)

Practical Chemistry. Adapted to the First Stage of the Revised Syllabus of the Science and Art Department. By J. Howard, F.C.S., &c. (London and Glasgow: William Collins, Sons, and Co., Limited, 1881.)

THE first-named of these books is a really good text-book for laboratory use; the experiments are clearly described; most useful "laboratory hints" are given; conclusions are carefully drawn from the experimental data obtained. The methods for proving the definition of boiling point, for illustrating the manufacture of sulphuric acid, and for confirming quantitatively the equation $KClO_3 = O_3 + KCl$, are especially to be praised. The student who works through this book will have laid a good foundation on which he may afterwards build; only let him skip those parts which deal with "chemical philosophy." Why should he begin his chemical career by learning that "combining weight" is synonymous with "atomic weight" (p. 31)? Why should he trouble himself with committing to memory the "atomicity" of the most important elements as given on p. 27 of this book? Why should he draw from the statement of Avogadro's law the erroneous conclusion that "the molecules of all gases are of the same size"? Why should he deceive himself by fancying that the formula N—O—N (p. 143) gives him accurate and well-grounded information regarding the molecule of nitrous oxide? No good reason can be given for doing any of these things, therefore let the student use this book as a laboratory guide only, and he will doubtless find it a trustworthy guide.

Could Mr. Howard's chemical philosophy be separated from his directions for conducting experiments, his book might also be recommended to the student of practical chemistry.

Although this book deals with laboratory experiments, one is much tempted to think that the author does not really regard chemistry as an experimental science. He deals with the general principles of chemical science too much from a literary point of view. An instance of this method is found in the preface, where we are told that "in former editions . . . the notation of Dr. Frankland was alone used. . . . In the present edition, however, it has been thought advisable to give, in addition, the notation and formulæ used by Professors Roscoe, Williamson, Thorpe, and others." This sentence is decidedly humorous; it connects so closely phenomena which appear to the student of chemistry to have but little in common.

Authoritative statements from the text-books exert a great influence on the author of this book; witness a sentence on p. 62: "A molecule must have all its bonds engaged, that is, it cannot combine with any substance without altering the arrangement of the atoms. Hence, there must always be an even number of *bonds* in the molecule of any element or in any compound." Nitric oxide is of course formulated as N_2O_2; no hint is given that the molecular formula of this gas is NO.

The first few pages contain many excellent examples of the misuse of that much misused word "force."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Primitive Traditions as to the Pleiades

MR. JUSTICE HALIBURTON'S letter of December 1 (vol. xxv. p. 100) will have been read by many as calling attention to a curious subject. As it refers especially to me, and indeed arises out of my remark on the story of the "Lost Pleiad" in Dawson's "Australian Aborigines" (NATURE, vol. xxiv. p. 530), I now write a few lines in reply. But it will not be possible to discuss properly Mr. Haliburton's ideas as to the Pleiades till he publishes them in full, with the evidence on which he grounds them. It must not be supposed that the subject has been unnoticed till now by anthropologists. That the Pleiades are an important constellation, by which seasons and years are regulated among tribes in distant parts of the world, that they are sometimes worshipped, and often festivals are held in connection with their rising, that their peculiar grouping has suggested such names as the "dancers," or "hen and chickens," and that numbers of myths have been made about them—all this has long been on record, though in a scattered way, and at any rate it is well known to students. Mr. Haliburton's letter shows that he has new information to add to the previous stock, and furthermore that he has formed a theory that the Pleiad beliefs go back to a marvellously remote period in the history of man, when these stars were, as he says, the "central sun" of the religions, calendars, myths, traditions, and symbolism of early ages. If the astronomical evidence is to support so vast a structure as this, it need hardly be said that it must go far beyond what Mr.

Haliburton mentions in his letter. But when his contemplated book is published, he may be sure of his facts being appreciated and his theories fairly dealt with. Though, as I have just said, this cannot be done here, I may be allowed one suggestion. Mr. Haliburton is good enough to speak of me as being a cautious person. May I in that capacity express a hope that verbal coincidences, when not close enough really to prove connection, may be kept out of an argument which ought to go on a more solid footing. Why should the name of the star *Alkyone* have anything to do with the name of *Alkinoos*, king of Corfu? They look indeed rather more alike in Mr. Haliburton's letter, where the latter name is misspelt with a *y*, but doubtless this is a slip of the writer or printer.

A word about my remarks on the Pleiades-myth which has led to this correspondence. The question is only a small one, belonging to comparative mythology, whether a particular Australian tale about the Pleiades, one of a dozen such known in that quarter of the world, is a genuine native myth or a spoilt version of a story borrowed from the white men. I doubted its being genuine, because it says that the lost one of the seven was the queen or chiefess. This is hardly according to nature, for we should expect the star supposed to have gone away to be one of the insignificant ones of the group, not such a bright one as a story-teller would call the queen. Of the many Englishmen who have heard of the "Lost Pleiad" it is curious how few know the probable explanation of the classic tale, as a nature-myth derived from the difficulty of making out more than six stars with the naked eye. It has been suggested by some that there may have been a loss of brilliancy in one of the smaller stars of the group since ancient times. If any of your astronomical readers think there is anything whatever in this supposition, it would be interesting to have their judgment on it.

EDWARD B. TYLOR

Fumifugium

IN justice to Evelyn it ought, I think, to be made known that Mr. Shaw Lefevre was entirely wrong in stating at the opening ceremony of the Smoke Abatement Exhibition that "Evelyn proposed as a remedy for the smoke of which he complained, that the use of coal should be prohibited in the City and neighbourhood of London." "Fumifugium" (which was printed in 1661, and not in 1644) is of course extremely rare, and even the editor of the reprint which was issued in 1772, and is now rare, calls the original "this very scarce tract," so that the way in which the blunder in question has been repeated, is perhaps not to be wondered at.

As a matter of fact Evelyn only mentions the idea of supplanting coal by wood to call it "madnesse," and he then goes on to say: "But the *Remedy*, which I would propose has nothing in it of this difficulty, requiring only the Removal of such *Trades* as are manifest *Nuisances* to the City, which I would have placed at further distances, especially such as in their Works and Fournaces use great quantities of *Sea-Coale*, the sole and only cause of those prodigious Clouds of *Smoake* which so universally and so fatally infest the *Aer*, and would in no city of *Europe* be permitted, where men had either respect to Health or Ornament," thus recognising the two points of view so well represented by the cooperation of the National Health and Kyrle Societies. "I propose, therefore," he continues, "that by an *Act* of this present *Parliament*, this infernal *Nuisance* be reformed; enjoyning that all those *Works* be removed five or six miles distant from *London*, below the River of *Thames*, &c., &c." Although this has been done to a considerable extent, we may, I think, on a foggy day, agree with Evelyn when he says that "the City of *London* resembles the face rather of *Mount Ætna*, the *Court of Vulcan*, *Stromboli*, or the suburbs of *Hell*, than an assembly of rational creatures and the imperial seat of our incomparable *Monarch*."

W. H. CORFIELD

Jamaica Petrel

THIS bird, known locally as the "Blue Mountain Duck" or "Booby Duck," appears in a carefully compiled list of the birds of Jamaica, by Prof. A. Newton and his brother, the Hon. Ed. Newton, Colonial Secretary of Jamaica, published in the "Jamaica Handbook, 1881, p. 117, as follows:—"PROCELLARIIDÆ—*Œstrelata jamaicensis*, Bancroft, Jamaica Petrel. *Procellaria jamaicensis*, Bancroft, *Zool. Journ.* v. p. 81; Blue Mountain Duck, Gosse, "Birds of Jamaica," p. 437 (Hill); *Pterodroma caribbæa*, Carte, *P.Z.S.* 1866, p. 93, Pl. x." During certain seasons of the year it is remarkable that this sea-bird should be found in holes under trees and in burrows on the Cinchona plantations and in the unfrequented woods of the Blue Mountain range, at elevations from 6000 feet to 7000 feet. The natural inference was that the birds make their nests on these places. But, although careful search has been made during the last two years, and a reward offered for nests, eggs, or any signs of nidification, nothing whatever has been found in that direction. It is therefore very probable that the birds use these holes and burrows simply as resting-places during the day, from whence they sally forth at night to their feeding-grounds at sea. The latter is distant only, as the crow flies, about twelve or fourteen miles. The birds are found in their burrows chiefly during the months of November, December, January, and March. Sometimes two lie in one hole, and dogs easily find them; but it has been noticed that the birds are always full grown, and with no apparent nest. I have been led to send you these remarks in the hope that possibly some of your readers with a wider knowledge of the habits of petrels might be able to give some clue as to the locality and general character of their nesting-places.

D. MORRIS

Botanical Department, Jamaica, November 14

Biology in Schools

MANY eminent biologists seem to think that there are insuperable difficulties in the way of sound biological instruction in public schools. Possibly my experience in this connection may be of interest. I began to teach biology some ten years ago. Two years' experience satisfied me "that the power of repeating a classification of animals with all the appropriate definitions has any thing to do with genuine knowledge is one of the commonest and most mischievous delusions of both students and their examiners." For the third year I prepared a series of laboratory notes sufficient for the dissection of a few plants and animals. Since the publication of Huxley and Martin's admirable text-book of biology we have used that as a laboratory guide. Through the liberality of the School Board we are provided with eight of Beck's students' microscopes. We begin with the study of the torula; we then take in succession the following organisms:—Protococcus, amœba, bacteria, mould, stone-wort, ferns, flowering plants, infusorian fresh-water polyp, clam lobster, and frog. We devote to laboratory work one hour daily for seven months. At the end of the course come morphological and physiological generalisations. Our classes number about eighty, and are divided into working sections of sixteen each. The average age of the students is sixteen years, rather more than half of them being girls. I have found the students eager and enthusiastic, and a large majority of them regret the untimely end of their study of biology. To enter college a lad needs between four and five years' work in Latin, and, if a scientific student, about five weeks in botany. Most of our high schools accept this estimate of the value of a scientific training, and only do the little that is necessary for the pass examination.

GEO. W. PECKHAM

Biological Laboratory, Milwaukee High School, Milwaukee, Wisconsin

A Natural Ant Trap

LAST June I was staying at Husum, in the Lærdal Valley, Norway, and observed on the almost precipitous sides of the valley facing the south, immediately behind the station-house, a considerable number of the red German catchfly (*Lychnis viscaria*). The plants were growing luxuriantly at an altitude of some 1000 feet above the bed of the river, and were just then showing a gorgeous array of blossoms. On plucking some of the flowers I became aware of a most unpleasant stickiness around the stems; in some instances the glutinous secretion being powerful enough to support the whole weight of the stem when I inverted and opened my hand. Thereupon I carefully examined more than a hundred plants, and was somewhat surprised at finding, on quite 95 per cent., either the dead bodies of a large species of ant, or individuals in all stages of dying. Some flowering stems had only one dead or dying ant upon each; others had two; others three; whilst others again had as many as seven or eight. Some ants had, as it were, simply lain down in the glutinous matter and succumbed without further struggling. The heads of others, firmly imbedded in the treacherous stuff,

with the rest of the body stiffened and suspended in mid-air, testified to violent and prolonged resistance. Some ants again had the body arched up, as if to avoid contact with the stem, and the legs only were fatally caught.

As is well known, the glutinous or sticky tracts lie around the stem directly beneath the nodes, and are about half an inch or more in depth. These glutinous zones are absent from the nodes, which are lower down on the stalk. But a darkening of the colour, just similar to what one sees below the sticky nodes, suggests the probability of these non-sticky nodes having been sticky at some former time.

I can find no reference in the ordinary books to the fact that ants visit, and die upon, this plant. In Smith's "English Botany," 1800, however, occurs the following remarkable account of *Lychnis viscaria*:—"Stem straight, about a foot high, simple, angular, leafy, dark brown, and clammy under each joint, by which insects are plentifully caught, as in several other plants of the pink or campion tribe, for what purpose no one has yet ascertained; probably their decaying bodies form an air which is salutary to vegetable life." As I do not quite understand the author's meaning in the latter part of his remarks I naturally forbear criticising the statement, and mention it here merely to show the opinion of a botanist on the subject eighty-one years ago.

On each flowering stem there are from two to four sticky nodes. I found that the majority of the deaths had occurred in the first zone of stickiness; fewer in the second, and still fewer at the higher nodes. Those ants therefore which gained the summit of their ambition would be pre-eminently strong and lusty, for to have arrived at the top of the plant among the flowers, they must have waded through morasses, each of which was sufficient to cause the death of many of their comrades. I found very few ants at the summit of the flowering stalks, and those that I did find there alive showed, from their want of vigour and restlessness, that they had been severely tried by the ordeals through which they had passed. The plant was growing in very rocky soil, each specimen quite isolated from any surrounding vegetation; so that I am satisfied that no ants, on the plants I examined, could have gained the summits by adventitious aids.

Time and the want of proper apparatus prevented my making some experiments I wished to have tried, and as I do not know when again I shall be able to pursue this most interesting investigation, your kind insertion of this may perhaps induce some of your readers to pursue the subject further. These are amongst the questions which have occurred to me:—(1) Is there any attraction in the glutinous secretion, or does the attraction lie in the flowers? I saw no ant-hills or nests anywhere in the neighbourhood of the flowers, and my impression at the time was that the ants had come a long distance. I scrutinisingly examined the ground, and, to my astonishment, found that almost the only ants on the spot were upon the plants. (2) How is it, if these sticky zones are simply to prevent ants and other small walking animals from getting to the flowers, that they do not occur at the lower part of the stem as well as higher up? (3) What injury, if any, do ants cause to this plant? (4) Is it likely that the plant derives direct benefit from the deaths that take place upon it? Is there, in short, any digestive action in the glutinous secretion, and any absorptive power in those portions of the stem where it is found?

I brought home some specimens showing the dead bodies of ants stuck to the flower stalks, and these were exhibited at the last meeting of the Linnean Society. I shall be happy to show them to any who are interested in the subject. J. HARRIS STONE

11, Sheffield Gardens, Kensington, December 2

Solar, Gas-Flame, and Electric-Light Spectra

IN answer to Mr. J. Hopkins Walters' inquiry contained in NATURE, vol. xxv. p. 103, the spectroscope declares that all these three spectra have for their base a continuous strip or band of light; in the case of gas-flame (the bright part) crossed by the sodium lines only; in that of the sun by the well-known Fraunhofer dark lines; and of the electric (arc) light by the bright lines of carbon. The illuminating power of each of these sources of light is thus shown to be due to the incandescence of their several solid and gaseous constituents, concerning which a volume might be written. The relative effect of the sun's bright golden glare, the gas-flame's duller yellow tint, and the electric-light's moon-like whiteness, on the optic nerve; have not, as far as I am aware, been yet made the subject of special research. Popular opinion assigns injurious results to the whiter light. Mr. Walters will find in "Photographed Spectra," on Pl. xv., Fig. 4, and the extra plate, the solar spectrum, and on Pl. v., Figs. 3 and 4, the spectrum of the electric arc between carbon points specially prepared to insure purity. In Dr. Marshall Watt's "Index of Spectra" the spectrum of the blue base of candle-flame is represented by the graphical diagram and description, Carbon I. The illuminating portion of a gas-flame presents in the spectroscope the appearance of a dull sun spectrum without the dark lines. J. RAND CAPRON

Guildown, December 3

Tele-dynamics and the Accumulation of Energy—their Application to the Channel Tunnel

A REMARKABLE opportunity is now presented to electrical and mechanical engineers of applying to eminent practical service the recent discoveries and advances made in relation to the accumulation and transmission of energy in the form of electricity. I allude to the construction and working of the Channel Tunnel Railway. Of course the direct application of steam-power to the work of boring is out of the question. The power employed in boring Mont Cenis and St. Gothard was transmitted by compressed air through metal tubes, but this is a very costly, wasteful, and in some respects inconvenient process; and this cost and waste increases in a very high ratio to the distance of transmission. Since those works were executed an immense advance has been made in the practice of transmitting energy by electric current, and particularly in storing that energy; and I predict that if the tunnel is ever completed (which I do not doubt) it will be by means of electrical agency. An eminent civil engineer, who had invented a boring-machine which he considered of great promise for that work, told me more than a year ago that Dr. Siemens assured him that he would undertake to transmit 50 per cent. of the initial power by electric current half way through the tunnel; and by this time he would most probably give a much larger percentage. An eminent French authority promises from sixteen to twenty horse-power by a single current over a distance of from ten to fifty kilometres. If these statements are founded on fact your readers will at once realise the applicability and potency of the agent. Then there must of necessity be an immense quantity of material to be carried to and fro. The electrical railways of Berlin, Brussels, and Paris have left no question open as to the easiest and most economical means of propelling the trollies; and by using several conductors as many trolly trains in succession could be run as there would be conductors. It would be premature to discuss now the subject of working this railway, but it is certain that electricity will be the agent, and there is very little doubt that the twenty miles of level tunnel way will be worked by energy generated and stored by the train itself in its descent from the land level to the tunnel level. An examination of this question in detail would be incompatible with your space and purpose. I will simply say that a train of 100 tons descending a gradient of 1 in 100 for five miles would start with a potential force of nearly 60,000,000 foot pounds, a very small portion of which would be expended in useful work. Let the surplus of this be applied not to destroying the rails by brakes and conversion into useless heat, but by revolving generators and storing the product to be used in again turning the generators (now motors) for propelling the train. I do not say that the train could be lifted up the five miles at the other end by this stored energy: the engineers may be intrusted with that duty. E. WALKER

DANTE AND THE SOUTHERN CROSS.—A correspondent inquires where Dante could have learned about the Southern Cross, to which there is evident allusion in the first canto of the "Purgatorio."

JAMAICA

OF all the West Indian Colonies appertaining to the British Crown, that of the Island of Jamaica can claim to be the largest in area, the most numerous in population, and the wealthiest in revenue. Within half a

century of being the oldest of the English possessions in the new world—Barbadoes was settled in 1605; Jamaica was capitulated in 1655—it has, though with many vicissitudes, been the most successful, and it has always shown strong signs of a healthy life, in that it has recovered promptly and well from its periods of misfortune. The extreme length of this fertile island is about 144 miles, while its greatest width is 49, and its least width 21 miles. Its surface is extremely mountainous, attaining a maximum in the Blue Mountain Peak of some 7360 feet. Of its superficial area of 4139 square miles only about 646 are flat, consisting of marl, alluvium, and swamps. It possesses numerous rivers and springs, and a fertile soil. Its total of population in 1861 was 441,264; in 1871, 506,154.

A Handbook to Jamaica, compiled from official and other records, has lately been published at the Government printing establishment at Kingston. It has been most judiciously edited by two members of the Jamaica Civil Service, and forms a volume of 450 pages, which deserves to be known to all interested in our colonies. Passing over the first two parts of the volume, which contain matter of chiefly local interest, the third part contains a chronological history of the island, with an account of its various parishes, its mountain ranges, lakes, and rivers, and an excellent sketch of its mineral resources, from which it would appear that the natural resources of the island have not as yet been satisfactorily explored. The fourth part is devoted to the consideration of the meteorology and climate, and of the birds, fishes, and insects of the isle.

Mr. Maxwell Hall is to be congratulated, that, after some opposition and under great difficulties, he has succeeded in some measure in establishing a system of daily weather reports, which are sent daily to the local press for publication. As the result of the reduction of a series of observations on the rainfall in different stations, and extending over periods of from five to fifteen years, Mr. Hall has been able to make out a certain systematic distribution of the rainfall over the island. It would thus appear that, while the May and October rains are everywhere strongly marked, the northern part of the island has winter rains in November, December, and January, the southern part has summer rains in August and September; and it would appear from the tables given that each part is further divided by the amount of the rainfall. Thus the north-eastern has the greatest rainfall; the west central comes next; the northern division third, and the southern has the least annual rainfall. Some such distribution, Mr. Hall thinks, was also existing at the time Sir Hans Sloane wrote his "Natural History of Jamaica" (about 200 years ago), and although he sees in the records of Sloane a change in the rainfall, yet he believes this to be not a constant change, such as might indicate a continually diminishing rainfall, but a variable change, probably systematic and periodic. On the question of the influence of forests on the rainfall, he decides that woods and forests are chiefly beneficial in reducing the range of temperature, and in maintaining the moisture of the ground, thereby preserving a constant supply of water for the springs and rivers. It may be noted that the central and uncultivated parts of Jamaica are still densely wooded, thereby aiding the constant river supply. Jamaica has two rainy and two dry seasons. The rainy seasons are in May and in October, lasting about two months, the intervening periods being dry. The climate may generally be described as a sedative one.

The Catalogue of the Birds of Jamaica is compiled by the well-known ornithologists Alfred and Edward Newton, the latter Colonial Secretary. Forty-three birds are enumerated as presumably peculiar to the island, that is to say, not known to have been found elsewhere. The list of the fishes is large. The river chub (*Labrax mucronatus*) is described as a "surpassingly delicious fish." Though fish abound in the seas, and each district has a sea-frontage, yet the yearly importation of cured "fish stuffs" of different kinds amounts in value to 200,000*l.* a year. To help and remedy this state of things the Jamaica Institute has offered a series of prizes for preserved fish.

The fifth and sixth parts treat of the economic botany of the island. The Government Surveyor, in reporting on the timber supply, estimates that there are at present about 800,000 acres of timber-producing forest in the island; that out of this there might be cut each year—without permanent injury—400 feet to the acre, say 320,000,000 as an annual supply; of this large amount only some 3,500,000 a year are actually cut for building purposes. About 166,000*l.* worth of fine timber was exported in 1880, but a large quantity of lumber and shingles is imported. This state of things Mr. Harrison accounts for by the difficulty of getting the timber out of the mountain fastnesses where it grows. He does not seem to agree with Mr. Hall on the subject of the change in the rainfall, for he declares that he has ascertained beyond doubt that forests exercise a great influence on it, that where the forests have been destroyed the rainfall has diminished, and he alludes to springs becoming dried up, and rivers that have ceased to flow. A very interesting list of some fifty of the woods of Jamaica, their qualities and the uses they are generally put to, is appended to this report. The island would appear to be a paradise for the fern collector, over 450 species being enumerated. Within a radius of five miles, taking Morce's Gap as a centre, over 200 species are to be found. The orchids are not so numerous, only 135 being named.

Of the main crops of the island, sugar still heads the list, the value of that exported in 1880 being 768,792*l.* The value of the coffee raised in the island in the same year is calculated at 381,595*l.* The coffee of the Blue Mountains is celebrated for its superiority, but a good marketable article is grown throughout the island. In a most valuable report by Mr. Morris, the present Director of Public Gardens strongly urges the propagation of the Liberian coffee, which was introduced in 1874. From the fact that this coffee will grow on the plains, where the preliminary expenses in the acquisition and clearing of land are lower than on the hills, where labour, too, is cheaper and more abundant, and where the difficulties and expenses of labour would be avoided, Liberian coffee possesses advantages not only over the Arabian coffee, but over almost any cultivation requiring the same capital and attention. Among the minor crops, that of the fruit crop is steadily and remarkably increasing in value, from 10,000*l.* in 1834 to 51,000*l.* in 1880. Jamaica tobacco is finding its way into the market. In the German markets—considered the most important for leaf-tobacco—Jamaica tobacco is well thought of, and in price ranks next to Havanna leaf, and since 1879 the consumption of Jamaica cigars in England has spread in an extensive manner. The cocoanut export, from a value of 3,357*l.* in 1870, has risen to 20,525*l.* in 1880. Ginger, pimento, and cacao are all successfully grown. The introduction of cinchona cultivation into Jamaica through a liberal supply of seeds sent in 1861 by Sir W. J. Hooker, promises to be a great success. For the year 1879-80 the quantity of bark shipped was 27,399 lbs., which realised the net sum of 5146*l.* From an elaborate report by Mr. Morris we take the following:—The plantations are estimated to cover nearly 400 acres; owing, however, to the practice of wide planting, the actual area occupied by regularly-planted trees is probably only a half of this. The advantages of close planting are undoubted. The climate of Jamaica would seem to be peculiarly well adapted for the successful cultivation of one or other of the various species of cinchona, at all elevations, from about 2500 feet to the Blue Mountain Peak itself. Thus *Cinchona succirubra* flourishes in the parish of Manchester at an elevation of

2700 feet, with a rainfall of about 120 inches and a mean annual temperature of 70° Fahr. This is perhaps the lowest elevation for the more valuable cinchonas at the Government plantations; the same species flourishes at 5000 feet, with an annual rainfall of 136 inches and a mean annual temperature of 60° F. The trees at this elevation do not seed freely, and it may be taken as the highest at which it would be advisable to cultivate the red bark in Jamaica. The range of cultivation for the valuable crown bark (*Cinchona officinalis*) is between 4500 and 6300 feet of elevation. It may here be convenient to refer to the department—that of Public Gardens and Plantations—which was newly organised in 1879. This department has under its control the Botanic Gardens at Castleton and Bath, the Park at Kingston, the Cocoanut Plantation at Kingston Harbour, and the Hope and Cinchona Plantation. The staff is directed by Mr. Daniel Morris, M.A., who had been assistant at the Ceylon Botanic Gardens. To an island dependent as Jamaica is for its prosperity on the produce of its soil, the importance of such a department is undoubted, and we trust that the new director will receive all due encouragement in developing the botanical treasures of the place.

The concluding parts of this most interesting handbook are devoted to the political constitution and parochial boards of the island; to the details of the various departments and colleges; to the statistics of population, crime, &c.; to the laws of quarantine, &c.; together forming a most useful volume of reference. There seems little doubt that if the capabilities of Jamaica were better known, it would attract the attention of settlers. There are surely as great attractions in bark or coffee-growing as in wool-growing, and Jamaica is nearer to us than the Australian colonies, and, with due precautions, as healthy a climate to live in.

OUR WINTER REFUGES—THE SOUTH OF ENGLAND[1]

II.

As regards temperature and rainfall the South of England, from Dover to Portland, presents a unique and well-marked winter climate, quite distinct from that of any other tract of the British Islands. The tract in question embraces the comparatively narrow belt, varying in width from two to ten miles, stretching between these two places and backed on the north by the sheltering range of the South Downs.

The rainfall in the east of England, from the Humber to Ramsgate, varies in the average annual amounts from 22 to 25½ inches; but on reaching Dover it rapidly rises to 30 inches, and from this point westward to Portland the rainfall varies only from 28 to 30 inches, the amounts differing within these narrow limits according to the flatness or boldness of the coast, and the character of the country in the immediate neighbourhood. To the west of Portland, along the coast, the rainfall rises considerably, and after passing Prawle Point, more rapidly to 44 inches at Penzance. Further, on striking inland from the coast towards and up the slopes of the Downs, the annual amounts increase to about 34 or 36 inches, on the high grounds separating the valley of the Thames from the lands sloping south to the channel; and from this ridge northwards it gradually falls to about 25 inches round London. Thus the Downs, as regards the rainfall and the winds, have important bearings on the meteorology of the south of England.

Equally decided are the temperature characteristics which mark off, climatically, these districts of England from each other. We may accept January as fairly representing the temperature peculiarities of the winter months. In this month the mean temperature of the whole of the eastern slope of Great Britain, from Wick to Dover, varies only from about 37°·5 to 38°·5, the temperature of the coasts being a little higher than that of the interior. But on arriving at Dover we encounter a January mean temperature of 40°·0, and from this point westward there is a steady increase, first slow as far as Worthing, where the mean is 40°·4, and then more rapid to Bournemouth, where the mean is 41°·2. On advancing inland upon the Downs, temperature falls much more rapidly than what is due to mere height, and this fall is continued in proceeding northwards towards London, the mean of which is 2°·5 and 1°·5 lower than that of Bournemouth and Brighton respectively. West of Portland the increase of temperature is still more rapid, the mean being 42°·9 at Torquay, 44°·6 at Falmouth, and 46°·2 in the Scilly Isles, the last temperature being the mean of London in the beginning of April.

Hence if the invalid requires a winter climate characterised by the combined qualities of mildness and dryness, such a climate must be sought for on the shores of the Channel from Dover to Portland. In the south-west a much higher temperature may be had, but the climate is there damper, and raw weather is of much more frequent occurrence; and in the eastern counties the climate is as dry, or rather drier, but the temperature of the air is from 2°·0 to 3°·0 colder.

The south coast possesses another climatic advantage of no small importance. The prevailing winds in the south during the winter months are west-south-westerly, and thus the winds which blow over the Isle of Wight pass on in the direction of London. Now we have seen that in passing from the Isle of Wight to London the mean temperature gradually falls 3°·0—the depression being due to the more rapid rate at which the land, as compared with the sea, is cooled down by terrestrial radiation. From this steady and continued lowering of the temperature of the south-westerly winds as they advance inland from the coast, it follows that haze and cloud are formed with greater frequency and of greater denseness as the winds successively advance into the colder districts. Hence the skies of the south coast are clearer and brighter than in the valley of the Thames—a consideration of the highest climatic significance in the cure of many diseases.

The generally light and porous character of the soil and subsoil along the south coast is a strong recommendation in favour of the sanataria of that region; because, as it affords a ready escape for the rain, the roads are quickly dry, and out-door exercise may be safely indulged in shortly after the rain has ceased. The generally bold character of the coast and sloping character of the surface is also advantageous as offering facilities for carrying out an effective system of drainage.

We have referred to the Downs as affording more or less shelter to the south coast from northerly winds, and to the Undercliff as a protection to Ventnor from north-east, north, north-west, and west winds (NATURE, vol. xxv. p. 33). Indeed the chief source of the advantages possessed by one of these watering-places of the south over another is the degree of protection it holds out from the deleterious effects of the easterly and north-easterly winds, and in some degree also to its distance from those parts of the Continent from which the east wind blows. Of the strictly local peculiarities which give one place a decided preference over another is the extent to which the district is planted with well-grown trees, by which the force of the winds, particularly east winds, is broken up and dissipated. In this respect the firs which have been planted in and around Bournemouth strongly recommend this sanatarium to the invalid, since, if fair overhead, he can almost always take outdoor exercise along the walks and promenades which are so completely sheltered by these evergreens. Bournemouth has the additional advantage of being to some extent protected from the full violence

[1] Continued from p. 34.

of the south-west winds by the South Downs of Dorsetshire, and also, though in a less degree, from the east winds by the Isle of Wight.

Since the averages here used are all for the twenty-four years ending with 1880 for the temperature, and for the twenty-one years ending with 1880 for the rainfall, the figures for these two chief elements of climate are strictly comparable throughout. The result is that all strong statements sometimes made in favour of local climatologies, such as the rainfall of Ventnor being as small as that of London, entirely disappear. Such differences could easily be found by the results of different terms of years suited to the purpose, being selected for the particular places whose climatologies are compared. All such comparisons, however, are not merely worthless, they are misleading.

It is, however, now indubitably shown that the south coast of England, from Dover to Portland, enjoys the best winter climate anywhere to be found in the British Islands as respects the two important qualities of mildness and dryness combined, and it is highly probable that the climate of the same tract has clearer, brighter skies, and consequently more sunshine, than elsewhere in these islands. In view of the results of Buchan and Mitchell's investigation into the weather and health of London (NATURE, vol. xxiv. pp. 143 and 173) it is evident that it is to the South of England the invalid who suffers from bronchitis, pneumonia, or other throat diseases, must look for the climate best suited in the treatment of his case, and that it is to the same climate, owing to its clearer air, brighter skies, and more frequent sunshine, that those suffering from nervous and mental diseases should look as more likely to give them the relief they are in search of.

TORNADOES, WHIRLWINDS, WATERSPOUTS, AND HAILSTORMS

I.

WHILE identical with and resembling cyclones in not a few of their leading characteristics, tornadoes and whirlwinds are yet in several all-important respects widely and radically different. The largest tornadoes are of so small dimensions when compared with the smallest cyclones as to point to a difference so decided that admits of no shading of the one class of phenomena into the other. Again, cyclones occur at all hours of the day, whereas whirlwinds and tornadoes are all but restricted to the warmer hours of the day, and perhaps altogether to the time of the day when the sun is above the horizon. Further, and intimately connected with the above, cyclones take place under conditions which imply unequal densities at the same heights of the atmosphere, whether these be due to inequalities in the geographical distribution of temperature or humidity; but whirlwinds occur where the air is unusually warm or moist for the time, and where, consequently, temperature and humidity diminish with height at an abnormally rapid rate. To put it otherwise, cyclones are phenomena consequent on a disturbance of the equilibrium of the atmosphere considered horizontally, but tornadoes, on the other hand, have their origin in a vertical disturbance of atmospheric equilibrium.

Hence whirlwinds are of occasional occurrence nearly everywhere, penetrating into regions where cyclones are altogether unknown; and even tornadoes, which are the most violent and destructive manifestations of the whirlwind, are phenomena either of rare or of frequent occurrence in nearly all climates.

Among the most remarkable of the tornado-swept tracts of the globe are certain portions of the United States of America; and to the examination of these the Meteorological Service of the States has given special attention by a systematic, careful, and minute observation of their attendant phenomena and their destructive effects. The results of these inquiries have been for some years recorded with great, but by no means too great, fulness and elaborateness in the annual meteorological reports of the Chief Signal Officer. Much has been done of late years, as our readers are aware, by observation and discussions of observations, to throw light on these atmospheric meteors; and in this connection we have the greatest pleasure in referring to Prof. Ferrel's recently published "Cyclones, Tornadoes, and Waterspouts," Part II., the portion of which, bearing on tornadoes and whirlwinds, is the most successfully handled part of that very suggestive work, and indeed presents the best theory of whirlwinds yet propounded.

Tornadoes, whirlwinds, and waterspouts are essentially the same, differing from each other only in their dimensions, their intensity, or in the degree in which the moisture is condensed into visible vapour; while the extraordinary downfalls of hail or rain, constituting the hailstorm and rainstorm, are simply the manner and degree of the precipitation. In the waterspout the main features of whirlwinds are best seen, owing to the degree, more or less complete, in which the vapour has been condensed into visible cloud through the whole length of the meteor.

Figs. 1, 2, and 3 represent different forms of the waterspout. In Fig. 1 is seen the black cloud covering the sky, from which a projection is let down from the cloud in the form of an inverted cone as at A, which continues to increase and extend downwards. The surface of the sea at D immediately beneath is soon seen to be stirred, and quickly thrown into a state of violent agitation. At this stage the whirling movement which originated in the clouds has extended downwards to the sea, and is doubtless continuous throughout, though the portion of the whirling column from A downward is not yet present to the eye by the condensation into cloud of its contained moisture. The cone at A continues to lengthen downwards, and ultimately reaches to the earth's surface as shown at B and C, and by the waterspouts of Figs. 2 and 3. As the whirling movements of the aërial column of the waterspout become more intensely developed, the increasing rapidity of the gyrations brings about increased rarefaction of the air within, with the inevitable result of increased condensation into cloud downward. The protrusion from the clouds and extension toward the surface of the sea of the waterspout is thus not due to the descent of vapour from the clouds, but to the visible condensation of the vapour of the spirally ascending air-currents arising from an increasing rarefaction due to the accelerated rate of the gyrations, the condensation being similar to that of the cloud seen in exhausting an air-pump.

The onward progressive motion of tornadoes and whirlwinds varies greatly, and is probably in all cases that of the general movement of that portion of the earth's atmosphere in which they are embedded and form a part. Tornadoes sometimes rage with destructive violence on heights and hill tops, while intervening valleys remain untouched, thus showing that they occasionally occur at comparatively small elevations, but do not reach down to the surface of the earth. It also sometimes happens that the tornado in its onward course rises for a brief interval above the surface and again descends. As soon as the rapidity of the gyrations of the column become diminished, the rarefaction of the air of the column and the condensation of the vapour are correspondingly lessened, and thereafter the waterspout gradually breaks up and disappears.

Under each of the waterspouts in Figs. 1, 2, and 3 the surface of the sea is seen to be more or less heaped up as well as in violent commotion, indicating that atmospheric pressure immediately under the gyrating column is less than it is all round. On land, when a tornado passes directly over a closed building, many instances have occurred when the whole building, walls and roof, has

been thrown outward with great violence, the wreckage presenting the appearance of a sudden explosion, proving that the pressure outside the building was instantaneously and largely diminished, and the building wrecked by the expansion of the air within. It is in this way that the tornado works no inconsiderable part of its most dreadful havoc in the destruction of human life.

During the storm of 1703, the greatest recorded in British history, it was observed that the roofs of many houses on the lee side of the buildings were wrecked as if by an explosion within. The destruction in this case was caused by the extreme rarefaction produced on the lee side of buildings by the mere mechanical action through friction of the terrific wind which swept past them. The records of tornadoes abound in illustrations of houses and other structures thus reduced to hopeless wrecks.

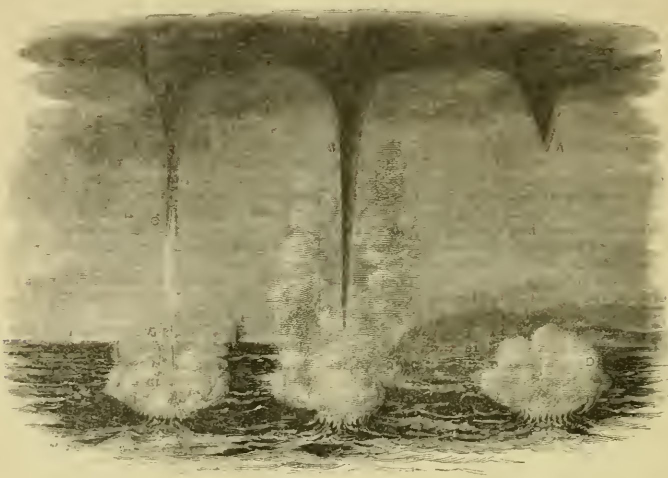

FIG. 1.

It is probable that the wind sometimes reaches a force in tornadoes exceeding what is ever reached in cyclones. During the tornado which occurred in Ohio on February 4, 1842, large buildings were lifted entire from their foundations, carried several rods through the air, and then dashed to pieces, some of the fragments being transported a distance of seven or eight miles; and large oaks nearly seven feet in girth were snapped across like reeds. This tornado sped on its course at the rate of thirty-four miles an hour, and at one place it did its fearful work in the brief space of a minute. During the tornado which swept over Mount Carmel, Illinois, June 4, 1877, the spire, vane, and gilded ball of the Methodist Church were carried fifteen miles to the north-eastward. On this incident Prof. Ferrel remarks that the ascending currents which could keep this structure suspended in the air for at least fifteen or twenty minutes must have had an enormous velocity.

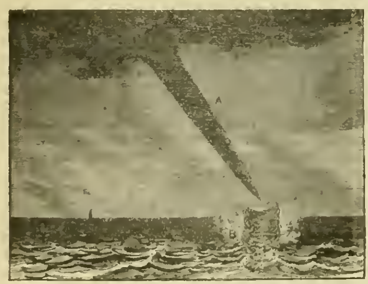

FIG. 2.

FIG. 3.

The usual position of the gyrating columns of whirlwinds is vertical, as seen in Fig. 1. Among other positions the column assumes a slanting direction as in Fig. 2, and a curved form as in Fig. 3. It is probable that to these latter forms many of those stationary or slowly moving dangerous squalls are to be referred that spring up with unexpected suddenness so frequently in such regions as the western lochs and islands of Scotland—

these sudden squalls which lash into a tempest of waves what is but a mere patch or narrow lane of sea, while all round remains like a sheet of glass, the squall being only the lowermost part of the gyrating column of a slanting whirlwind. Nothing is more surprising to the landsman who encounters one of these squalls for the first time than to see a mere bit of sea lashed into a tempest by say an east wind in which no sail can live, while but a short way to leeward other vessels are seen either under a good-going breeze or in calm water, altogether untouched by the tempest, which seems to blow directly to them, but which strangely never reaches them.

In examining cyclones, phenomena occasionally present themselves which strongly suggest the idea that they include within their circuit, as an independent meteor, the whirlwind or the tornado, the phenomena in question being most frequently met with in those cyclones which present, in close continuity, masses of air differing very widely from each other in temperature and humidity. Of such cyclones the great storm of October 14 last appears to be one. On that occasion the changes of temperature and humidity were sharp and sudden, particularly from the Grampians to the Cheviots, the great fall occurring when the wind changed to northward. As we have already stated (NATURE, vol. xxiv. p. 585), off the Berwickshire coast the darkness accompanying the changes of wind, temperature, and humidity was denser and more threatening than elsewhere, and almost simultaneously with the approach of these changes, a hurricane, or rather tornado, broke out with a devouring energy which bore everything before it. The tornado-character of the storm off Eyemouth is shown by the accounts of some of the survivors, who describe the wind as blowing straight down from the sky with an impetuosity so vehement and overmastering that the sea for some extent was beaten down flat into a stretch of seething foam, in which many boats sank as if driven down beneath the foam by the wind, while outside this tract the waves seemed to be driven up to a height absolutely appalling, which in their turn engulfed many of the boats yet remaining. Similar seas, with level wastes of seething foam, bounded immediately by waves of a height and threatening aspect never before witnessed, were encountered by several well-appointed steamers out in the middle of the North Sea during this storm, thus confirming the observations of the Eyemouth fishermen. These facts seem to point to one or perhaps more tornadoes of no inconsiderable dimensions, with slanting columns, the terrific force of the gyrations of whose lower extremities played no inconspicuous part in the devastation wrought during the continuance of this memorable storm.

(*To be continued.*)

SIR DAVID BREWSTER'S SCIENTIFIC WORK

BUT thirteen years ago there passed away from the roll of living scientific worthies one whose name will ever hold a high place for the variety and scope of the researches carried out with untiring zeal through a long and useful life. Since our last number the centenary of Sir David Brewster's birth has been commemorated in Edinburgh, and the occurrence forms a fitting opportunity to review briefly his multifarious work in the light of the science of to-day. Sir David Brewster was born in 1781. He must therefore have been twenty-five years of age at the date when his first published scientific memoir, entitled "Remarks on Achromatic Eyepieces" (published in *Nicholson's Journal*), saw the light. Until 1867 he continued actively to pursue scientific researches. Whilst his literary works are of themselves amply sufficient to cause the name of Brewster to be handed down to posterity, the long list of four hundred original memoirs which appears in his name in the Royal Society's Catalogue shows with what unremitting ardour the fire of discovery burned within his breast.

In the domain of Physical Optics Brewster was an eager and successful worker: and his industry was rewarded by a series of brilliant experimental discoveries. The genius of Young, the keen perception and quick acumen of Malus, and the trained intellect of Arago had been concentrated on this hitherto neglected department of science. But Brewster, who cannot be said to have possessed, either by birth or education, the powers of any of these investigators, discovered more than all of them put together, and by diligent observation unravelled complicated phenomena which baffled their powers.

In 1812, having heard of Malus's celebrated discovery of the polarisation of light by reflection, he took up the study of polarisation, and in the course of the next two years advanced our knowledge in various directions. He discovered the property of the agate to give a single polarised image; the polarisation of the rainbow; the polarisation tints in thin plates of crystal; the so-called depolarising power of mineral and other substances; and the partial polarisation produced by metals.

These discoveries he followed up immediately by several of equal interest. He observed the double system of elliptical rings of colour in topaz, and subsequently investigated the appearances presented by other crystals, both monaxial and biaxial in convergent polarised light. He not only discovered but determined the law of the partial polarisation effected by transmitting light obliquely through a bundle of thin plates of mica or glass. Meantime he was actively prosecuting literary work. His "New Philosophical Instruments," published in 1813, contained a great deal of matter new in the science of optics, the results of original research. Hitherto in tables of the refractive index of bodies diamond had stood at the head, and ice at the foot of the list. But Brewster showed that realgar and chromate of lead exceed the diamond in refractive power, whilst fluorspar, cyolite, and tabashear fall below ice both in refractive and in dispersive power.

During these and the subsequent years the disturbed relations between Great Britain and France prevented the workers in science on opposite sides of the Channel from learning what progress was being made, with the result that many of Brewster's discoveries were independently made by others. Thus Malus anticipated Brewster in the discovery of the "depolarising" effect of mica films, of the partial polarisation of metals, and of the polarisation effected by bundles of thin plates, though he missed the law of the last phenomenon. Arago also anticipated Brewster in finding the colours of thin crystal plates in polarised light. In 1814 and 1815 Brewster discovered a new relation of polarised light, namely, that existing between the ray and the state of mechanical strain of the body through which it passed. He observed that heated glass exhibited coloured tints in polarised light, and that Rupert's drops did the same. Subsequently he produced both double refraction and chromatic polarisation in soft and indurated jellies, in horn, and in a variety of animal and vegetable bodies, particularly in the crystalline lens of the eyes of animals, whose structure is thereby revealed. The most important of these early researches was undoubtedly the law connecting the angle of maximum polarisation by reflection with the refractive index of the body. The difficulty of establishing such a law was in Brewster's case enhanced by the circumstance that his mind was not a mathematical one. With a skill that rose superior to the defects of apparatus, and with an unflagging patience at which one can only marvel, he scrutinised with minute care every fragment of mineral in the cabinets of his scientific acquaintances. By this means he constructed tables of refractive and dispersive powers and of the polarising angles of the various reflecting surfaces. And from these two sets of data he brought out

the discovery of the tangent law now always identified with his name. But there were other occasions when some mere mathematician stepped in to take up the elaborate facts which Brewster had elaborated, and from them in a few minutes to deduce a law for which he took the credit of discovery. "It seems to us," writes Prof. Tait in an article which appeared in the *Scotsman* shortly after Brewster's decease, "that sufficient allowance has not been made for the natural irritation which such treatment was certain to cause, especially in a high-souled and single-minded man incapable of treating others as he felt himself treated. His biographer will have a painful, but a necessary and salutary, task to perform in gibbeting such thankless parasites. Many a much-praised scientific article—volume even—may be found where the facts are taken mainly from Brewster, though his name is barely mentioned. He was driven by such treatment into frequent disputes about priority, and in general he was successful, though often before the final settlement of the question the obnoxious paper had found its way to a non-scientific public, and even to foreign journals. It is always a difficult matter to determine what is the proper course for a philosopher under such circumstances. Few have the calmness to rely upon the almost invariably just decision of posterity; and most of those who do so go unrecognised to their graves."

In 1816 Brewster announced his discovery of the cause of the colours playing over the surface of mother-of-pearl, and of the possibility of transferring them to casts taken in wax, isinglass, and fusible metals. He also investigated the images and fringes of colour visible in some natural specimens of calc-spar, and turned his attention, though this time with only incomplete results, to the production of tints by multiple reflexions at the surfaces of polished metals. When in 1830 he returned to the subject, there resulted a remarkable memoir on Elliptical Polarisation, which appeared in the *Philosophical Transactions*. In 1817 he discovered the whole class of biaxial crystals, and triumphantly deduced the law of their action on light, thereby solving the difficulties which had perplexed Biot and Arago. He even sketched out a relation between the primitive forms of crystallisation of minerals and their optical behaviour.

His attention was next directed to the question of the absorption of light. In this department of science he made many observations. He was the first to observe in any systematic way the effects of absorption upon the prismatic spectrum. He reinvestigated the solar lines discovered by Wollaston and Fraunhofer, and observed even a larger number of them than the latter had detected. He made the important observation that many of these lines are due to absorption by the earth's atmosphere; and in one of the latest of his contributions to science—a joint paper by himself and Dr. J. Hall Gladstone, which appears in the *Philosophical Transactions* for 1860—he returned to the subject with unabated vigour and unsurpassed perspicacity of thought. He also discovered the power possessed by nitrous oxide gas to produce absorption lines, and he noted the great and extraordinary increase in their number and density when the gas is heated. "The power of heat alone to render a gas which is almost colourless as red as blood, without decomposing it, is in itself a most singular result; and my surprise was greatly increased when I afterwards succeeded in rendering the same pale nitrous gas so absolutely black by heat, that not a ray of the brightest summer sun was capable of penetrating it." Indeed he seemed to be here on the very verge of the discoveries on the spectroscopic significance of the width and frequency of the absorption lines which have been made by Mr. Lockyer, M. Janssen, and others during the present decade. In 1831 Brewster published his "New Analysis of Solar Light," the new analysis being nothing else than the operation of looking at the solar spectrum through coloured absorbent media. It was this series of experiments which led him to conceive the theory of the three primary colours which he so resolutely maintained against all opponents till his dying day. Through his red glass he could see light through a considerable range of the visible spectrum, and therefore, he concluded, there is some red in all parts, but with different degrees of brightness. The yellow and the blue were, he held, also distributed, each with a maximum of its own, throughout the range of the whole light. He believed that he had proved the conversion of blue rays into violet ones by viewing them through an absorbent medium. "We must remember," says Prof. Tait, by way of apology for the persistence with which Brewster clung to his pet theory, "that he trusted to an eyesight that had rarely deceived him—an eyesight once so perfect that he is one of but a very few who have *seen* the extraordinary ultra-red rays which he was the first to discover as visible light."

One of his researches connected the subject of absorption with his work on polarisation. He investigated the property known as *dichroism* possessed by a great number of coloured crystals, tourmaline, Brazilian topaz, and others, a property which has lately given rise to several important investigations by physicists in Germany and in England. He showed how the absorbed tints are altered by heating, and here he anticipated a point in the electromagnetic theory of light which was then of course quite undreamed of.

To enumerate the whole of Brewster's researches would occupy so many columns that only a few of the more prominent must now be adverted to. Optical illusions of sundry kinds, fluid cavities in crystals, polarisation of the sky, phosphorescence, fluorescence, photography, the optical properties of agate, opal, and labradorite, the magic mirror of Japan, and the theory of binocular vision, all claimed their notice and formed the bases of many careful researches. The experimental researches of Brewster in optics are in fact paralleled only by those of Brewster's great contemporary Faraday in electricity.

Brewster was the inventor of several well-known optical instruments. The *kaleidoscope*, which was brought out in 1816, created such a furore that 30,000 were sold in a few days. His *monochromatic* lamp appeared in 1823. In 1849-50 he brought out his lenticular *stereoscope* (an improvement upon Wheatstone's reflecting stereoscope of 1838), and a binocular camera, for use in producing stereoscopic pictures. Still more important, though far less widely known, was his discovery of the application of lenses and combinations of lenses to lighthouses. This was in 1812; in 1820 he was urging the adoption of his system on those in authority—two years before Fresnel, who usually gets the credit of this application, had begun his work.

His objections to the undulatory theory of light endured to the last, when he stood almost alone in his refusing explicit adherence to the theory. Trained himself in another school of thought, and accustomed through long years to the Newtonian theory, it is not remarkable that in the absence of mathematical predilections the mathematical intricacies of the fabric woven by Fresnel had little charm for him. And if we find it hard to realise the slowness of minds like Brewster's to receive the undulatory theory as an established truth, we may perhaps find no inapt parallelism in the repugnance felt even amongst some of the "crowned heads of science" at the present day towards entertaining the still more modern electromagnetic theory of light in which the undulatory theory is fast being swallowed up piecemeal.

Brewster's literary activity was simply extraordinary. He brought out the "Edinburgh Encyclopædia" between the years 1808 and 1830, writing many of the articles himself. To the seventh and eighth editions of the "Encyclopædia Britannica" he contributed the articles on Electricity, Magnetism, Microscope, Optics, Stereo-

scope, and Voltaic Electricity. No fewer than seventy-five articles in the *North British Review* are from his pen. From the year 1819 he was, along with Jameson, editor of the *Edinburgh Philosophical Journal*, in which so many of his researches saw the light. His "Letters on Natural Magic," his "More Worlds than One," his treatise on "Optics," his "Martyrs of Science," and his "Life of Sir Isaac Newton," all testify to an unremitting activity rarely equalled. He was made Principal of the University of St. Andrews in 1838, a post which he relinquished only in 1859 to succeed to the Principalship of the University of Edinburgh. As one of the founders of the British Association in 1831, no less than as a distinguished representative of science, he received the honour of knighthood.

A man who could unite so many varied qualifications in himself, who, besides adding so richly to the total of exact knowledge, could do so much to diffuse that knowledge to succeeding generations, who could write not only with the calm decision of a philosopher, but with the vivid imagination of a poet and even with the fervour of a preacher, must indeed be acknowledged to be a remarkable figure in the age in which he lived. His position in the physical sciences, standing as he did between the old generation of workers and the new, is not very easy to define. But his memory will doubtless descend to posterity in connection with numerous departments of the science of optics, in which his work remains to testify to his place amongst the men of science of whom Great Britain has just reason to be proud.

NOTES

THE Lord President of the Privy Council has appointed Prof. Archibald Geikie, F.R.S., to be Director-General of the Geological Surveys of the United Kingdom, and Director of the Museum of Economic Geology, Jermyn Street, in succession to Sir Andrew C. Ramsay, F.R.S., who retires from the public service towards the end of the present year.

MONDAY night was an enthusiastic Arctic night at the Geographical Society. The first paper was by Mr. C. R. Markham, on the important discoveries made by the *Rodgers* in and around Wrangel Land, and on the proposal that England should lend a hand to search for the missing *Jeannette*, and that a Government expedition should be sent out to look for Leigh Smith. Lieut. Hovgaard of the *Vega* also read an Arctic paper, detailing his plan for a *Jeannette* search from about Cape Chelyuskin as a basis; while an instructive paper was sent by the Dutch Commodore Janssens, on the ice-conditions in Barents Sea, and the probable position of Mr. Leigh Smith in the *Eira*. Of course Mr. Markham's energetic enthusiasm was infectious, and everybody seemed to agree that it would be disgraceful to England not to send out search expeditions. Sir George Nares and Sir Allan Young spoke, but it cannot be said that they threw much light on the problem; the good-natured Sir Allan took much trouble to say he knew nothing about these seas, and therefore he thought an expedition should be sent out for the *Eira*. Mr. Grant, the well-known Arctic photographer, told his experiences on the ice of the Barents with the Dutch and with Mr. Leigh Smith during the last four years, and he seems to think, what every one else thinks, and what is evident, that Mr. Leigh Smith is locked up in the ice somewhere. But all the speakers on Monday night evaded the main point, which was clearly stated in Mr. Eaton's letter in last week's NATURE (p. 123). Mr. Eaton declares that Mr. Smith went out with the deliberate intention of wintering, and that he has now provisions to last two years, Of course, in cases of doubt, it is well to take the worst possible view. But there seems to be a conflict of evidence. Mr. Eaton, than whom no one ought to know better, positively states that the *Eira* is provided as we have indicated; while on the other side there are vague and inconsistent statements. Were we convinced of the real danger of the *Eira's* situation, we should heartily support a relief expedition; but in this case there seems to be no doubt. The matter may be safely left in the hands of the Admiralty, who will doubtless look at the situation all round, and take care that they do not commit themselves, at the most, to more than a mere search, in conjunction, we should suggest, with relatives and friends. But on consideration of all the evidence, it may not be thought sufficient to warrant Government intervention. We were pleased to learn that the object of the Dutch in sending out expeditions year after year to these seas is to obtain a thorough knowledge of the movements of the ice before they venture to send out a fully-equipped expedition to force its way northwards; this is thoroughly scientific in its method.

A BALLOON accident, which we fear may turn out unfortunate, occurred in the South of England last Saturday. Capt. James Templer, Mr. Walter Powell, M.P., and Mr. Agg Gardner, ascended at Bath on Saturday at 1.55 p.m. for the purpose of taking the temperature of the air, and the amount of snow in the air, for the Meteorological Office. Capt. Templer, in a letter to Mr. R. H. Scott, describes what followed: "I cleared the snow clouds at 4000 feet altitude; the temperature of these clouds was 28°, and the wet-bulb thermometer read 26°. At 4200 feet we passed over Wells, the time being 2h. 50m. At this height I worked over Glastonbury; the temperature now rose to 41°, and the sky was perfectly clear. I passed then between Somerton and Langport, and I here found that I was in a N. ½ W. current. I asked Mr. Powell to send the balloon up to 6000 feet to ascertain the temperature of a small bank of cirrus. I found this temperature to be 31°, and then I asked him to place me at 2000 feet altitude, to regain the N. ½ W. current, and we then came in view of Crewkerne. I now kept at a low altitude until I reached Beaminster. Mr. Powell here observed that we were going at thirty miles an hour, and here we first heard the roar of the sea. The balloon suddenly rose to 4000 feet; at this time I said to Mr. Powell, "Go down to within 100 feet of the earth, and ascertain our exact position." We coasted along close to the ground until we reached Symondsbury. I here called to a man and asked him how far the distance was to Bridport, and he said about a mile. I asked Mr. Powell to prepare to 'take in,' our pace now increasing to thirty-five miles an hour. To avoid the little village of Neape Mr. Powell threw out some ballast. This took us to 1500 feet elevation, and we had still two miles to get in. I opened the valve and descended, about 150 yards short of the cliff. The balloon on touching the ground dragged a few feet, and I rolled out of the car with the valve line in my hand. This caused the balloon to ascend about 8 feet, when Mr. Gardner dropped off, and unfortunately broke his leg. I found that the rope was being pulled through my hands, and I called to Mr. Powell, who was standing in the car, to come down the line. He took hold of the line, and in a few more seconds the line was torn through my hands. The balloon rose rapidly. Mr. Powell waved his hands to me, and I took his compass bearings, and found that he was going in a S. ½ E. direction." Capt. Templer lost no time in getting into a steamer at Weymouth and searching the Channel in the most likely direction, but without result. Up to the present nothing has been heard of Mr. Powell, and the worst is to be feared. This accident is certainly to be regretted, more especially as the expedition was in the interests of science. Still in spite of the accident the Meteorological Council are to be congratulated upon the endeavour to get at the correct facts of the air.

IN the *Comptes Rendus* for December 5, 1881, p. 936, there appears a paper animadverting on the meteorological stations it has been proposed to establish in the neighbourhood of the

North Pole, which paper, according as it is looked at, is provocative either of amusement or amazement. It is amusing to read that it is all the way from the equator that these cirrus clouds travel, giving us Europeans, by systems of vorticose movements let down from their lofty heights, our cyclones, our rains, our thunderstorms, our hail, and even our snow; that, towards the elucidation of the great problems of the movements of the atmosphere in their bearings on climate and weather, the observations made forty years ago by Lottin, Martins, Bravais, &c., in the Arctic regions, are quite sufficient for the purpose. The additional data to be expected from the Arctic network of stations now proposed to be established at Bossekop, Jan Mayen, Navaja Zemlia, Spitzbergen, &c., being quite insignificant; and that the French meteorologists in agreeing to establish, as their contribution to this extensive research into the movements of the atmosphere, a station near Cape Horn, supposed, as assumed by M. Faye, that this station near the antarctic circle, would assist them in framing weather forecasts for France. It is amazing to see it quietly assumed that the fishermen and sailors on the French coasts have no practical, or at least personal interest in the storms which sweep across the British Islands and Scandinavia; and to read the explicit statement that in the interests of the seaports of France, and of science itself, what is above all things needed is the organising of a first-class meteorological station (*une grande station météorologique*) in the Azores. With regard to this, French sailors and fishermen may be thankful that other counsels rule the action of those who are entrusted with the preparation of weather forecasts for their country and with the investigation of those laws, a knowledge of which will enhance the value of this branch of practical meteorology.

In his inaugural address at the opening of the Session of the Sanitary Institute, Dr. Alfred Carpenter dwelt upon the necessity of such an organisation, as proved by the lamentable ignorance of the mere elements of sanitary science shown by many of the candidates for the diploma of the Institute, most of them already official guides of health and other bodies. It seems strange to be told by Dr. Carpenter that there is a feeling of antagonism to the Institute in the Social Science Association. The former is the practical outcome of the latter, and the Association ought therefore to rejoice that its teachings have borne such desirable fruit. The Institute is certainly doing much good, and there seems to be no doubt that by its action and by other means, a beginning has been made in this country of a thorough sanitary reform.

An instructive case of injury from lightning, on a gentleman's estate near Geneva, is recorded by M.. Colladon (*Arch. des Sciences*, September 15). The lightning first struck a tall poplar standing near an iron-wire fence; thence the fluid passed to an elm standing close to the fence on the other side, damaged three main branches of this, and wounded the trunk on the fence side, down to a point opposite the top wire of the fence. The course was then along this wire, but only, it appears, in one direction, viz. towards an iron gate a little way off, under which passed the pipe which supplied gas to the house. The wire, a double one, was fused in some parts. After damaging the gate the current found its way to the gaspipe (making a hole in the ground), and passed along this to the house, injuring no part of the pipe-system of that, but only a piece of ornamental rose-work containing iron wire in the ceiling of the drawing-room over the lustre. Thence it passed to earth by the iron pipes and wires on a balcony outside the room. Several bushes near the poplar and fence were affected (coloured brown), and the plate on the collar of a dog which was attached to a wire between two shrubs, and had been heard to howl at the time, had disappeared. The extended character of the discharge and the influence of wires seem to be salient points in this case. M. Colladon advises making the parts of telegraphic or telephonic wires that pass near a house double or triple the mean thickness, so as to diminish the chances of lateral discharge.

M. Plateau has studied the phenomena of the bursting of bubbles. When a bubble bursts it disappears almost instantaneously, leaving behind it a multitude of small liquid drops. The order of the phenomena is really as follows:—The bubble begins to burst at one point, the film rolling away in a circle around the opening, and its edge becoming a rapidly-enlarging liquid ring. This ring draws itself together into segmental portions, which ultimately become small spherules. At the same time the contraction of the rest of the bubble causes a rush of air through the aperture, and blows off the spherules into the air with a kind of small explosion. The phenomena are best observed by blowing a bubble of glyceric solution upon an iron wire ring, and then bursting it at the top by touching it with a needle whose point has been dipped in oil.

The conduct of competitive examinations in China seems to be farther from perfection than might be expected in the case of such an ancient institution. The *Peking Gazette* contains a memorial from one of the censors complaining that the matsheds which are erected at the entrance to the examination hall in the capital to issue tickets of admission to competitors are frequently overturned by the rush of applicants, that an unseemly crowding and snatching of tickets from the officials take place, and that candidates break the rule prohibiting them from leaving the compartments in which they are isolated during the examination. They are allowed, he says, to fetch their food themselves (examinations in China last from thirty-six hours to three days at a stretch) from the kitchens, and they meet and converse freely. Prepared essays, the memorialist fears, are passed in from outside during these hours by the student's friends. Again, when the lists of successful candidates are posted up, a tumultuous crowd assembles outside the gates; bands of the unsuccessful ones obstruct the progress of the chief examiner, employing threats and entreaties to prevail on him to alter the lists. The censor also protests against the length of time frequently taken before the results of an examination are known. The Chinese examiners, however, have an excuse for this which our own Civil Service Commissioners have not, viz., the number of students examined; at the triennial provincial examination held in Canton in 1879 there were 10,160 candidates for 82 degrees!

The death is announced of Mr. William Bramsen, a Danish gentleman whose acquirements in Japanese scholarship were extensive. During a residence of more than twelve years in Japan Mr. Bramsen devoted his leisure to a study of the language, chronology, and numismatics of the country. His principal work is "Japanese Chronology," published in 1880, the only complete treatise on the subject which has ever been written. In this laborious work Mr. Bramsen has given the exact day of the month and year corresponding to the Japanese dates for the past thousand years. He has further explained the complicated systems by which the Japanese and Chinese reckoned time, and has thrown out the suggestion that in the early periods of Japanese and Chinese history the year included the time between the equinoxes, and did not correspond to our year. This idea he has supported with much learning, and should it on further examination turn out to be correct, it will revolutionise our notions of the antiquity of the Chinese and Japanese peoples. During the past year Mr. Bramsen was engaged in producing in parts a beautiful work on Japanese numismatics. Only the first part, dealing with recent copper coins, had been published. A few weeks ago he read a paper on the subject before the Numismatic Society of London. His collection of Japanese coins was the most complete private collection in existence, and was, we believe, valued by himself at about 2000*l*. He

was not much past thirty at the time of his death. It was his intention to return to Japan so soon as he was called to the English bar. The main characteristics of his work—which was but an earnest of what might have been expected from him had he been spared—were thoroughness and care. It will be difficult to fill the important, and in some sense peculiar, position which he occupied in the field of Japanese scholarship. He was a member of the Royal Asiatic Society, and of numerous native and foreign societies in Japan.

THE Brighton Health Congress and Domestic and Scientific Exhibition are being held this week. The Exhibition, over which Lord Chichester presided, was opened on Monday. The Congress, over which Dr. Richardson, F.R.S., presided, was opened on Tuesday evening by the delivery of his inaugural address. Dr. Richardson spoke on the "Seed-time of Health," pointing out the perils that beset youth in the present condition of hygienic education, and empirical and unscientific practice. The sittings of the Congress will be continued until to-morrow. The Congress is composed of three sections. The first, presided over by Mr. Edwin Chadwick, C.B., relates to the Health of Towns; the second, presided over by Mr. J. R. Hollond, M.A., M.P., relates to Food; and the third, presided over by Dr. Alfred Carpenter, C.S.S., relates to Domestic Health. A large number of important papers are down for reading and discussion, including, amongst others, essays on slaughter-house reform, by Mr. H. T. Lester, B.A.; food-plant improvement, by Major Hallett; sanitation in decoration, by Mr. Robert Edis, F.S.A.; food preservation by cold, by Mr. T. B. Lightfoot; recreation spaces in large towns, by Dr. Fussell; bread reform, by Miss Yates; cheap food and longevity, by Dr. Drysdale; rational feeding, by Mr. Wynter Blyth; diet in public institutions, by Dr. Whittle; home sanitation, by Mr. H. H. Collins; a comparison of English and foreign watering places, by Mr. H. S. Mitchell, M.A.; health lessons in schools, by Mr. Charles Cassal, B.A.; clothing and health, by Mrs. E. M. King; and papers by Sir Antonio Brady, Dr. Browning, Edward Easton, C.E., Ellice Clarke, C.E., Messrs. Stephens, E. Bailey Denton, and others. Yesterday the Mayor and Mayoress held a reception in the Pavilion. To-day, Dr. Taaffe, Medical Officer of Health for Brighton, delivers a public lecture. On Saturday, excursions will be made to various places of interest in and about Brighton, and in the evening of Saturday, the proceedings of the Congress will be brought to a close by a lecture to the working classes from Mr. Brudenell Carter, F.R.C.S., on the subject of Eyesight. The Exhibition is on a most extensive scale, including objects relating to food; domestic, labour-saving, and educational appliances; house sanitation; industrial dwellings; lighting, electrical and kindred inventions; decorative art, such as photography, painting on china; horology; and a very extensive loan collection of great value from the South Kensington Department.

AT the meeting of the Sanitary Institute on December 7, Dr. Alfred Carpenter in the chair, the adjudicator, Dr. W. Farr, F.R.S., and Dr. Richardson, F.R.S., reported that the Wyatt-Edgell prize of 200*l.* for an essay on the Range of Hereditary Tendencies in Health and Disease was awarded by them to the essay bearing the motto "The subtlety of nature far exceeds the subtlety of reason." On the sealed envelope accompanying the essay being opened the chairman announced the author to be George Gaskoin, of 7, Westbourne Park. The prize will be presented by the Rev. E. Wyatt Edgell at the next ordinary meeting, February 8. The inaugural address was delivered by Dr. A. Carpenter, vice chairman of the Council.

ALL the members of the Royal Commission on Technical Instruction have returned to England. The chairman, Mr. Samuelson, M.P., remained at Paris for some days in order to obtain additional information on the general policy of the Department of Public Instruction. The selection of the members of the Commission, on account of their acquaintance with different branches of the inquiry, has proved very useful, Dr. Roscoe having been able to devote his attention more particularly to chemical technology, Mr. Philip Magnus to school organisation, and Mr. Slagg, M.P., Mr. Woodall, M.P., and Mr. Swire Smith to the bearing of technical instruction on the branches of industry with which they are familiar. It is proposed to take the evidence of experts in this country in February, and to visit Germany, Switzerland, and Belgium in the spring.

M. PASTEUR has been elected to one of the vacant seats in the French Academy.

PROF. FLOWER has just been appointed by the President and Council of the Royal Society a trustee of Sir John Soane's Museum in the vacancy occasioned by the death of Sir Philip de Malpas Grey Egerton, M.P.

WE have received from Messrs. De la Rue and Co. their pocket and desk diaries for 1882, together with beautiful cards and almost microscopic registers for use during the coming year. If possible all these are more beautiful examples of the printer's art than those produced in past years, and especially interesting from NATURE's point of view, at all events in the fact that the amount of scientific facts packed into the closely-printed page is greater than ever. The mechanical equivalent of heat, the present magnetic elements, the mean distance of the sun, and such like data, are all to be found in their proper place, while the astronomical portion is so full that the amateur astronomer will be spared many references to his *Nautical Almanac.*

ON Friday last took place the first distribution of prizes and certificates to the successful students in the various schools connected with the City and Guilds of London Institute. The Report showed the rapid increase of candidates at the examinations of the Institute, and Sir F. Bramwell gave an address, explaining what was meant by technical education, and the great benefit which must accrue to the various industries by the application to them of the scientific principles on which they were based.

SOME severe shocks of earthquake, accompanied by loud detonations, are reported by the *Valais Gazette* to have occurred at Sion and Sierre on Sunday the 4th inst.

WE learn on good authority that M. Cochéry is preparing a project for the protection of cables and the general regulation of telegraphy. It will be laid before the French Chamber of Deputies after the end of the recess, which will begin in a very few days.

A "SOLAR" locomotive has been placed on the French Northern Railway. It is so called owing to an electric light which is placed in front and fed by the engine itself, and intended to illuminate the way for a long distance in front.

A GEOGRAPHICAL and Natural History Exhibition has recently been opened at Gotha. It will close on the 20th inst.

THE additions to the Zoological Society's Gardens during the past week include a Pomatorhine Skua (*Stercorarius pomatorhinus*), British, presented by Mr. George H. Baxter; two Kestrels (*Tinnunculus alaudarius*), British, presented by Mr. F. Usher; a Horrid Rattlesnake (*Crotalus horridus*) from Brazil, presented by Dr. A. Stradling, C.M.Z.S.; a Dwarf Chameleon (*Chamæleo pumilus*) from South Africa, presented by Major Hunt; a Common Jay (*Garrulus glandarius*), British, presented by Mr. J. Young; two Cape Crowned Cranes (*Balearica chrysopelargus*) from South Africa, a Giant Toad (*Bufo agua*) from Brazil deposited; a Red Kangaroo (*Macropus rufus*), two Mocassin Snakes (*Tropidonotus fasciatus*), born in the Gardens.

SOLAR PHYSICS[1]

I.

I HAVE to address you in this course of lectures on what we know of the infra-red end of the spectrum and its relation to solar physics. I will commence by asking a question, and endeavour to answer it in such a way as will, I hope, be understood. The question I propound is, How do we know that there are any rays below the red rays of the spectrum? In answering the question I would beg you to remember that every body in motion possesses what we call energy, or a capacity for doing work, be the motion a wave motion or a direct motion. Let us take one or two examples of waves: first, that of water, which is familiar to us. I need scarcely point out that a wave of the sea is capable of doing an immense amount of work, not to say mischief; there is no doubt, then, that it is capable of doing work, and this we may take as the true definition of energy, existing in a body, viz. the capacity of doing work. Whence, then, does a wave derive its energy? Perhaps we may have to travel many miles from the place where we find our wave. Travelling to the origin of the waves, we shall no doubt find that a wind has generated them, and in reality it is the energy possessed by the wind which is carried by the waves to the distant shore. The energy possessed by the wind has not been directly expended on our coast, but when transmitted by the waves this same energy is applied in different manner, and by this difference in application it becomes effective. We all know, for instance, that a child may ring a church bell if he give a pull at the right intervals of time, and so, by timing the impact of waves correctly, it is possible for them to do work which in any other way would be impossible. Another example of the energy of waves is the tuning-fork, as in the experiment which Mr. Lockyer showed you. You will recollect that he demonstrated that if one tuning-fork was brought near another of the same pitch the second took up the vibration of the air. The tuning-fork which was struck, or bowed, generated waves in the air carrying some part of the energy of the vibrating prongs to be expended on the second tuning-fork, and as this tuning-fork vibrated in the same period as the first one, each blow of the air-waves was essentially well-timed, and the fork was thus set in motion. You will also recollect that a a fork not of the same pitch—that is, not sounding the same note—was unable to cause vibration in the second fork; and this was simply because the energy was applied at wrong intervals of time. In the case of the tuning-fork, then, the air is the medium through which this energy was conveyed.

With light we have the same kind of motion in the luminiferous ether: the motions of the molecules swinging in the source of light may, for the sake of illustration, be looked upon as composed of an infinite number of tuning-forks, the ether, instead of the air, carrying their energy in all directions. How can the energy in the ether show itself? In the first place it must meet with some obstruction, and secondly that obstruction must be capable of vibrating with it, and thus damp or destroy the waves. The destruction of the wave motion in the ether is known as the absorption, and thus we see that where there is absorption there work of some kind must be done. The work, then, that light can perform is this. [When I say light, I say it with a definite object. It has been said that it is nonsense to talk about dark light; but it is no more nonsense to talk about dark light than to talk of a white violet, a yellow rose, and so on. Therefore, I prefer to call the whole ether vibrations with which we are acquainted, light, until we get a more authoritative definition.] The work that light may perform then is this, it may cause certain appliances in our eye to vibrate (and perhaps also cause chemical decomposition on the colouring matter of some membrane which is placed near the retina), which gives us the sensation of vision. Secondly, it may cause the molecules of the material body on which it falls to vibrate more freely than they do when in a normal state of vibration, and thus raise the temperature of the body. (It must be recollected that physicists suppose the molecules of all matters to be in active vibration, and a rise of temperature simply means an increase of those molecular motions). In the third place it may cause the atoms which compose the molecules to vibrate more energetically than they do under ordinary circumstances, and cause one or more of the atoms to swing off, as it were, and thus create a new molecule; in other words, cause a dissociation of the molecule. We may sum up our definition by saying that the presence of light can be known by three distinct kinds of work. It may be known by its causing the sensation of vision; it may be known by a rise in temperature of the body on which it falls; and it may be also known by the chemical action which it induces. I think, then, we have an answer to the question which I propounded, How can we tell that there are rays which exist below the visible red of the spectrum? If they exist, they must be shown by a rise in the temperature of any body which may absorb those rays when placed in their path, or by their chemical effect. That they do not give rise to the sensation of vision I need scarcely say.

The dark rays were discovered in the years 1800 and 1801 by Sir William Herschel, who was investigating the solar surface with a telescope. Finding that the heat sent to the eye was unbearable, he wished to obtain some medium to cut off those particular rays which gave the heating effect. In order to do that he undertook a series of investigations of the spectrum, in what we should now call perhaps a rough kind of way, in a manner which I will show you on the screen. A beam of light was passed through a prism fixed horizontally against a slit in a wall, being bent so that the spectrum fell upon a table beneath, on which he ruled lines marking the boundaries of the colours. On a sloping board turning on castors he placed three thermometers in a line, two of which he caused to lie within the spectrum, the third remaining outside it. He then noted the height of the mercury in all three of the thermometers, and thus compared the two in the spectrum with that lying beyond it (I may say that the diameters of the bulbs of the two thermometers in the spectrum, which is rather an important point, were one-eighth of an inch and half an inch respectively). Not only did Sir William Herschel use thermometers, but he also used the principle of absorption to increase their indications, for he blackened those thermometers with China black. He found he got a greater effect by using lampblack than by using the bare bulbs of the thermometers. He commenced by placing his two thermometers in the violet, and he found he got a certain rise of mercury. Having made a scale in accordance with the ruled lines on his table, he set up at the point indicating the violet an ordinate also to scale, showing the number of degrees of rise in the thermometer at that particular point. Then in the indigo he set up another ordinate indicating the degrees of rise there, and so on at all these different points; so that he was able to construct, as it were, a mountain of the heat effect due to the spectrum in all parts (Fig. 1). Having gone in this way over the

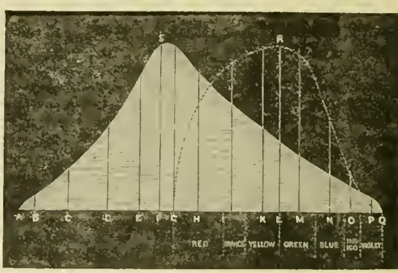

Fig. 1.

whole of the visible solar spectrum, he found there was a rise in the two thermometers, as he approached the red from the violet. (It must be recollected that before his time there was no knowledge of any rays which existed below the red). He therefore ruled lines on his table beyond the red, and having reached the limit of the luminous spectrum, he shifted his thermometers beyond, and found that they rose even higher than in the red. This led him to continue the experiment, and he found by going a long way beyond the red he still got a slight trace of rise in the mercury of his thermometers. By this means he was able to construct his well-known curve (which answers to a curve of energy) in the very simple manner shown in Fig. 1. I shall have to refer to this curve in another lecture, and I want you to fully bear in mind that the heights of every part of this curve answered to a comparative measure of the energy of the particular parts of the spectrum—

[1] Lecture delivered on May 25, 1881, at the Lecture Theatre, South Kensington Museum, by Capt. Abney, R.E., F.R.S.

in other words, to the comparative heating effect of different parts of the solar spectrum. Thus you see that Sir William Herschel, by the use of thermometers, was able to discover that there were rays existing below the red, and this he did by the second method, viz. by noting the rise of temperature in the absorbent body, lampblack, placed in the path of the rays. There are other modes of showing a rise in temperature in lampblack, amongst others by the thermopile, and to that I shall have to refer more at length in a subsequent lecture, and therefore I pass on at once to the chemical effect of the different rays of the spectrum.

In order to show you how we can arrive at a knowledge of the existence of energy in the different parts of the spectrum by their doing chemical work, I must take you through one or two very simple experiments, experiments which I dare say you may have heard of before, but the sight of which perhaps may impress your minds more than if you merely read of them. The first experiment will show the effect upon chloride of silver. I have in this frame a piece of paper impregnated with chloride of silver, and behind this screen, which I have had erected to save your eyes, is a Siemens electric lamp, which gives out a very intense light indeed. A lens placed at a proper distance from the points will cause an image of them to fall on this paper. After a few seconds' exposure you see that where the image fell we shall have a darkening effect; in fact we have an image of the arc printed on the chloride of silver paper. Now this paper apparently to all casual observation is white; what rays of the spectrum are they then that cause this blackening effect? By and by we shall have to find out to what this blackening is due. I have here some chloride of silver in collodion, and with this I think we shall be able to see what rays they are which affect the chloride of silver. In front of the slit of this spectroscopic arrangement we place this chloride of silver, and you will remark that the image of the slit cast by the prism on yonder white wall is of a lemon colour, and that the violet of the spectrum is much subdued in intensity. The true colour of chloride of silver in that particular state in which it exists in the paper then is that which absorbs the violet, and from what has been said on the principle of work being done where absorption takes place, we should expect to find that it is the violet rays which discolour that chloride of silver, and not the yellow rays, which, as we saw, passed freely through it. We will prove that. I have here a blue glass, and we will see whether we can print through the blue glass in the same satisfactory manner that we can when the light is unshaded. Placing a yellow glass in front of the light, first you see that there is no action whatever—the paper remains perfectly white. Now, taking the blue glass, and trying to print through it, you see we have a print of the arc—not perhaps quite so deep as where the unshaded light acted on the paper, but still sufficiently so to show that the blue and violet light are effective. The proposition enunciated then in this case is correct, that the rays active in the dissociation of chloride of silver are the rays it absorbs. But we may consult the spectrum still further, and, by placing such a piece of paper directly in it, and allowing it to print, we shall find that the chloride of silver is only attacked by the blue and violet rays, and not at all by the yellow. Such, you see, is the case in the photograph before you. There is an invisible part of the spectrum beyond the violet by which the silver chloride is even more affected, but that is a region of the spectrum with which I will not trouble you, as it is beyond the scope of my lectures. It will be seen then that we have a specimen of the chemical decomposition of a solid body. Now I should like to show you what is the cause of that darkening; namely, how the chloride of silver is changed. I am obliged to use chemical symbols, because they are short, but I will try to explain them. In ordinary chemistry the chloride of silver is designated AgCl, Ag meaning one atom of silver, and Cl meaning one atom of chlorine, which are joined together. But in order to explain phenomena which are met with in photography, silver really requires two atoms of chlorine to be combined with it to form chloride of silver; that is silver is a *diad* element. This I have expressed by this symbol which I have here, $Ag''Cl_2$; that is two equivalents of chlorine are obliged to be combined with one equivalent of silver. I will give the reason why the old formula is not perfectly correct: when you have light acting on chloride of silver, work of some description is done amongst the atoms of the molecules forming it, and we have one atom of chlorine thrown off by the vibrations of the blue part of the spectrum, and the new molecule $Ag''Cl$ is what is formed, which will grasp any other unsatisfied atom or molecule which may come in its way. In chloride of silver, then, we have an example of the decomposition of a solid body by the action of light. I have here two bottles, both containing ethyl iodide, a body which we will say roughly is composed of ethyl and iodine combined together; the action of light on this is to cause the iodine to separate from the ethyl, and the iodine liberated colours the liquid, as we have it in one bottle. The other bottle is ethyl iodide unaltered by light. So that you see we are obliged to shield this liquid from the light in order to prevent it from decomposing into ethyl and iodine. Here we have decomposition of a liquid by light.

I will now endeavour to show you the decomposition, or dissociation, which is perhaps a better term, of the molecules of a gas, and its combination with something else. I have here a jar of chlorine, and I think you will see by holding it in the rays of the spectrum that we have certainly the violet cut off, and a good deal of the blue. Therefore, if we find any work can take place within this chlorine it must be by those rays which are absorbed or cut off. I have here a jar of hydrogen which is perfectly colourless, and were I to put that in the spectrum I should teach you nothing, because the whole of the rays would pass through it. If then I have a mixture of hydrogen and chlorine together, and allow light to act upon them, it is quite evident that the only matter which can be acted upon is the chlorine. Now, in these small glass bulbs which are covered with yellow paper, are equal volumes of chlorine and hydrogen. When chlorine and hydrogen are combined together we have what is known as hydrochloric acid, a gas of the same tenuity as a mixture of the two. It has been found by practical experiment that if you have an intense source of light acting upon chlorine and hydrogen a combination between these two at once takes place, and we have the hydrochloric acid formed with a violent explosion—not enough to do any harm, but one which will make the room echo. Now our conception of the matter is this, that no hydrogen atom can exist by itself; that there must be two atoms to form hydrogen molecules; and that there must be at least two atoms of chlorine to form a chlorine molecule, perhaps more. Anyhow, you cannot have less than two atoms to form one molecule of chlorine, or less than two of hydrogen to form a molecule of hydrogen. If then we have these two mixed together, and cause light to act upon them, what is the physical result? The physical result is that the atoms of chlorine will swing violently apart from one another, they will be dissociated, and in their swing will catch up one of the atoms of hydrogen, and hydrochloric gas will be formed. Now you saw that the mixture of chlorine and hydrogen, or rather that the chlorine itself cut off the blue; in other words, it was the blue light which would have any chemical effect upon the mixture. I will now get Mr. Greening to allow the Siemens light to act through red glass, and you will see, I think, that there will be no effect whatever. Now, directly he takes it away there is a violent combination of the two with an explosion. To show that it is the blue light that is the effective light we will cause those two gases to explode by means of white light filtered through blue glass. I may say that the arrangement is very simple. We have the Siemens light; a lens brings the rays from that Siemens light to a focus on the centre of the bulb, and the vibration of the ether proceeding from those points causes those two molecules to combine in the way that you saw just now. We will put the blue and yellow glasses together first, and start the Siemens machine; when we draw away the yellow glass we have the same result as before.

For photographic purposes silver salts are the most convenient; if, however, we had to wait until the silver salts visibly darkened before we obtained a photograph, we should have to wait much longer than it is in the experience of all that we have to do. I will try and explain what happens when a very short exposure is given to a silver salt. For certain reasons silver chloride is not used, but we have recourse to silver iodide or silver bromide, and in some cases where both are used together a better result is obtained. What happens to these salts by a short exposure? What happens to silver chloride when acted upon by light? You will remember I told you that (with our notation for silver) after light had acted on silver chloride we had one atom of silver combined with one atom of chlorine. In the same way, if we replace the chlorine by iodine we have sub-iodide of silver formed. The visible image and the image impressed by a very short exposure are identical except in the quantity of matter altered. We will suppose, for instance, according to the modern theory that each of these molecules are charged with electricity,

with one kind of electricity. These sub-molecules, the sub-iodide and the sub-chloride, are unsaturated compounds, and are ready to join hands with any body for which they have the least affinity. Suppose then we have a solution of a silver salt, say of silver nitrate, and that we introduce some body which will precipitate that silver in a metallic state, and suppose again that one atom of silver as it is precipitated is charged with one kind of electricity, it is quite within the range of probability that the silver atom, as it is precipitated in the solution, may be attracted by the sub-iodide of silver when charged with another kind of electricity, and so form a new molecule as it were. This built-up molecule will not be fully satisfied, but probably have an excess of the opposite kind of electricity, with which the sub-iodide was charged, and the silver atoms which were oppositely charged to those first attracted would in their turn be attracted, and so on until the image is, as it were, built up on the small quantity of sub-iodide first formed by the action of light. In the case of silver bromide we have the same thing happening. We have sub-bromide of silver formed, which is represented by one atom of silver, and one of bromine, Ag″Br, and it is quite within the range of possibility that another body may be brought in contact with that, which, being charged with electricity opposite in polarity to that with which this molecule is charged, may attract away, as it were, the bromine, and thus leave the metallic silver itself behind. This is what happens really in the case of what we call alkaline development. In the first case we had acid development, or an image built up by the deposition of silver from silver nitrate, and in the other abstraction of bromine from the small quantity of sub-bromide of silver which is formed by the action of light. The image so built up, however, would scarcely be apparent, since the metallic silver thus formed would be inappreciable to the eye. Another phenomenon seems, however, to present itself, and that is, that the atoms of metallic silver, and of the unaltered bromide of silver, are oppositely charged with electricity, and combine to form fresh sub-bromide of silver; these new molecules of sub-bromide are reduced, and so the action goes on till an image is built up, each molecule of sub-bromide originally formed by the action of light forming a nucleus for the reduction. If instead of forming the iodide and bromide of silver in collodion films, as is usually the case now, we form iodide and bromide of silver on a metallic silver plate by allowing iodine and bromine vapour to have access to it, and if, after exposure to light, we allowed mercury vapour to act upon it, then the same kind of action would take place, the condensed mercury vapour would be attracted to those points which had been acted upon by light. That is the earliest form of photography, and was known as daguerrotype.

I now propose to show you a practical demonstration of the two methods of development of which I have shown you the outlines by diagrams. First, I will ask you to notice the part of the spectrum which the silver iodide plate cuts off. I have placed such a plate in front of the slit of the lamp, and you will see the blue is cut off. Iodide like chloride cuts off the blue rays, but with more intensity than the chloride. Where there is absorption there alone can work be done, the blue rays are therefore most effective in altering iodide of silver. I have a photographic spectrum apparatus placed in position. We have the Siemens light as before, a collimating lens (about which I need not enter into details), a prism through which the light has to pass from the slit, and here we have a lens and an ordinary camera. I propose to place a plate coated with silver iodide in the spectrum of the arc, and another coated with bromide, and then develop them if possible on the screen before you by the two methods of development. The first plate we expose is an ordinary wet plate, *i.e.* we have a collodion film which covers the plate, and this collodion film contains iodide of silver, and it is moistened with nitrate of silver. We will expose that to the spectrum for a second. I have in front of the slit at present a solution of bichromate of potash, which cuts off the blue, and therefore the light passing through would have no effect on the plate. I withdraw the front of the slide, and give a very short exposure. Now we will take a cell, F, containing what we call a developing solution, that is, something which will precipitate metallic silver from the soluble nitrate of silver; we will place it upon the stand of the lantern, B, and by means of the lens G we shall see a reversed image of part of the cell on the screen. I next place a piece of yellow glass, E, in front of the lantern lens. I take the plate and simply immerse it in the solution, and by degrees you will see a blackening take place. I am afraid the film is a little too intense—it is now coming out more rapidly and more vigorously; and here we have the image of the blue end of the spectrum perfectly developed. I will get my assistant to take charge of this, and in the meanwhile I will throw on the screen another spectrum which was taken in a similar manner.

Now we will try the other mode of development, which I hope will be more visible to the audience than the one we have tried. We will use the Siemens light again to form the spectrum. We will keep the yellow solution in front to cut off the blue rays whilst focussing it, and then I am perfectly safe. Then we will remove the yellow solution, and give a very short exposure, and we will develop by the alkaline process. We will use the same apparatus as before for developing. We have here a cell containing the liquid which has a great affinity for bromine, and I have no doubt we shall find that the solution will take away the bromine and leave metallic silver behind. It will probably be rather slower than the other in appearing. The plate is now placed in the cell, and we see the lines of the spectrum are appearing, and finally the image is fully out. I now withdraw the yellow glass.

You may ask how it is I can afford to let the light fall on th plate without causing a further deposition. The fact is, this solutio

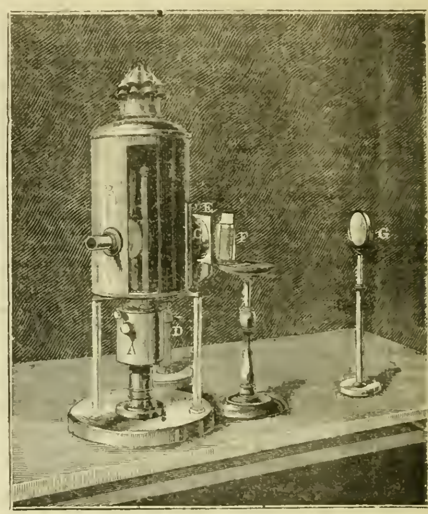

Fig. 2.

itself is coloured red,[1] and therefore the light passing through it has no effect on the bromide. I daresay by and by, when those pictures are thrown on the screen, you will be able to see what kind of spectrum we have got. You will remember, then, that we have in these methods of development which I have endeavoured to bring before you two kinds of chemical action—one a physical action of attraction exercised by sub-iodide of silver, the other a chemical one by the taking away of bromine from the silver salt.

The first mention that we have of a photographic spectrum in the red or below the red was in the year 1839, when Dr. Draper published a paper saying that he had been able to observe certain lines in the solar spectrum below the limit of the red. I propose to show you on the screen a copy of his photograph, and explain how it was taken. Dr. Draper proceeded in this way. He took a daguerreotype plate, exposed it to light first, then exposed it to the spectrum. In Dr. Draper's spectrum we have the whole of the blue and violet part of the spectrum delineated, but in part of the green and all of the yellow there is a blank, but be-

[1] The plate was developed by ferrous oxalate.

low these the lines in the red A and B in the red are shown; but still lower down there are three lines delineated, which he calls α, β, γ. Recollect the way he proceeded. He exposed the daguerrotype to light, and he allowed the spectrum to fall upon it. What was the meaning of that? The meaning of that was he altered the iodide of silver to begin with. I have here a piece of iodide of silver paper. One half has been exposed to light, and the other has not been exposed to light at all, and you will see the difference in colour. One has a greenish brown tint, and the other a decided yellow. The yellow you saw cut off the blue; the brown tint, if you put that in the spectrum, would allow the yellow to pass, but would cut off not only the blue but also some of the red too. How then do we explain this action? It is true he found that these lines, A, B, α, β and γ, had impressed themselves, but he found they were what we call reversed lines, that is to say, what ought to be black before were white, and what ought to be white before were black. How can this be explained? The spectrum was the same, the iodide of silver

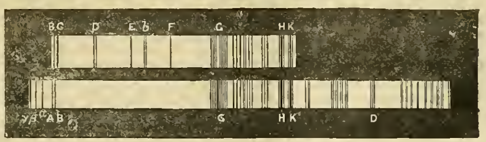

Fig. 3.

plate was the same. All was the same except the previous exposure to light. Now, this remained unexplained for a long time. It was supposed there was a certain antagonism between the rays, that is to say, that the red rays were able to undo the work which the blue had done, and that the yellow remained neutral. But was this an explanation? There can be no such thing as antagonism of energy in this matter, and therefore it required some further explanation.

In investigating the subject it fell to my lot to try experiments on the constitution of the photographic image, and my experiments led me to find that what was supposed to be antagonism of rays in the red part of the spectrum to those of the blue was nothing else but another chemical action which was called into play.

I have here a negative of a line drawing. I place a collodion plate containing iodide of silver in contact with it, but before I develop it I will place half of it in a solution of peroxide of hydrogen, which is an oxidising solution, and on developing I find only half the image has appeared, viz. the part which was not placed in the oxygen peroxide; to adopt the old explanation, there is an antagonism of the peroxide of hydrogen to the action of light! This gave a clue to Dr. Draper's reversal of the image which he got in the red rays of the spectrum. I will show you what it occurred to me did happen. Dr. Draper's plate after it had been exposed to light contained molecules of sub-iodide of silver, and when he allowed the spectrum to play upon it the sub-iodide of silver was anxious to obtain anything it could to satisfy itself, and so took up oxygen from the air and formed an oxy-iodide of silver, Ag″I, combined with oxygen, and that oxide of silver was totally incapable of development. Why? Simply because its energy of attraction was satisfied; there was nothing to attract the mercury condensed from the mercury vapour by which his image was developed. This then might be an explanation of Draper's photograph which should be capable of proof, and in order to prove it I will show the way I proceeded. I will take a plate of iodide of silver and expose it to light before you; then I propose to immerse it in a cell containing an oxidising solution of very delicate peroxide of hydrogen, which, as we know, is a very strong oxidiser, in fact one which will give up oxygen very freely to anything brought in contact with it. I have an arrangement by which I can do that, consisting of a dark slide in which I can put the cell and the silver plate. *Here* you see the prepared plate in its normal state. The electric light is allowed to act upon it, and of course the iodide of silver will be reduced to sub-iodide. I shall next allow the spectrum to play on the plate whilst immersed in this oxidising solution, and see if we cannot get the same results that Draper did in his reversed spectrum. If the theory that I give of the production of Draper's oxidising photograph is correct, then the red light ought to aid the oxidation of the photograph, or rather of the subiodide, forming that oxyiodide of silver which I mentioned to you. I will leave the bichromate cell in front of the slit in order that you may see the blue rays have nothing at all to do with the matter. I will give rather a longer exposure than I did before, and in that way I think I shall be able to get a result. I will give it to my assistant to develop, and then throw it on the screen as soon as he has finished with it. Now what shall we expect to find in this photograph? If the red rays help the oxidation of the iodide we shall expect to find that where the red rays are active no development whatever will have taken place, and as a fact that is really what we find. This method of Draper's, of photographing the ultra-red part of the spectrum, is exceedingly inconvenient, as it requires a long exposure, and, I may say, is unsatisfactory, because it gives very bad definition. You have to use a very open slit in order to get it.

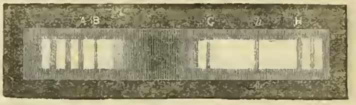

Fig. 4.

I now throw on the screen a portion of the *solar* spectrum taken in the way I have just carried out before you. In it you will see a facsimile almost of Draper's photograph. The question arises, what would happen suppose the plate was immersed in a deoxidising solution such as potassium nitrite? We have the answer at hand in the shape of a photograph so exposed. The reversal, you see, is entirely absent.

Now the question comes, Is it possible to show the existence of the ultra-red rays of the spectrum by visible means? in other words, by the exposure of any surface to the light? I think I can show you that it is possible by Balmain's phosphorescent paint. If I expose this to the light of the electric lamp we shall find that of course it will become very luminous indeed. Now when I expose this luminous surface to the action of the spectrum something ought to happen, perhaps which will give us an idea of Draper's photographs. I will try, and then I must pass round this luminous plate, because you will not be able to see it at a distance. I bring the light to a focus on the slit of the spectroscope, and place the surface of the paint, which is still luminous, in the spectrum for a short period, and now I will pass it round, and you will be able to see the phenomena; first of all a bright patch, and then a black patch beyond. The bright patch is caused by the blue rays; the black patch beyond is caused by the ultra-red rays, the red rays and the yellow rays; in other words, these rays have the property of quenching the vibrations of the phosphorescent particles, so that you see we have a means of showing visibly the existence of the ultra-red rays of the spectrum.

Our knowledge of the value of the photography of the spectrum, as regards its most refrangible portion, was very limited indeed until Mr. Lockyer took up the subject of spectrum photography with earnestness. In the year 1872 at Chatham we also began our researches in this matter, and we hoped that what we had found to be so immensely valuable in the violet and the blue regions of the spectrum—we might also be able to accomplish for the red and ultra-red rays of the spectrum as well. In the year 1872 Vogel made an important announcement, which, if it had proved everything one could have wished, would have left no need for further experimentation. He said if you took a bromide of silver plate or iodide of silver plate

and covered it with a dye, that in the spectrum, where the dye absorbed, there a photographic action, although beyond the usual boundary of photographic action, would be seen. We followed up this very carefully, hoping to find some dye by which we might be able to photograph the ultra-red rays of the spectrum. Had I known as much then as I do now I should not have followed any such chimerical idea. But what Vogel stated was perfectly correct, viz. that in that regions of the spectrum which certain dyes absorbed, a photographic action would take place. Suppose I take a plate prepared with some silver salt, and flow over it a dye, and then expose it to the spectrum; I find where the dye absorbed there a photographic image was formed. What was the meaning of this? This required investigation as well. The first dye that was taken up was that of cyanin blue. I have here a plate covered with cyanin blue, and when this plate was placed in the spectrum it was found that it bleached in the yellow, No. II. Fig. 5. Now what was the meaning of that bleaching in the yellow? Let us consult the absorption spectrum of cyanin blue, to see whether it absorbs in that particular part of the spectrum; for if it absorbs in that particular part there work must be done as I have already shown you. I will throw the spectrum on the screen, and then introduce a solution of cyanin blue in front of the slit of the lantern, No. I. Fig. 5. We do this, and it will be seen that there is great absorption in the yellow, so that that particular portion of spectrum bleached the cyanin blue which the cyanin blue cut off. So that work and absorption went hand in hand: when the action was investigated more closely, it was found

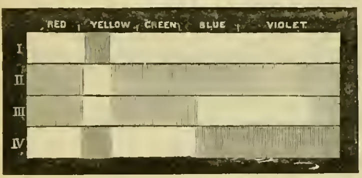

FIG. 5.—I., absorption spectrum of cyanin blue; II., bleaching effect of spectrum on paper stained with cyanin blue; III., bleaching effect of spectrum on a silver bromide film stained with cyanin blue; IV., photographic impression of spectrum prepared as in III. The shaded parts show metallic silver on development.

that the work performed was an oxidation; in other words, that bleaching took place through the effect of oxidation. So much for cyanin blue, *per se;* when, however, we took a plate covered with bromo-iodide of silver in collodion, and dyed with cyanin blue, exposing it for some time to the spectrum, it was found not only that the cyanin was bleached in the yellow, but it was also bleached in the blue, No. III. Fig. 5. It should be remembered that the only factor of difference was in the first case we had cyanin blue, in the collodion by itself, and in this last the dye and iodide and bromide of silver. What then was the explanation of this? That required a further investigation, and I think, perhaps, I shall be able to show you what really did happen. I will take that same cell of cyanin blue used before, and place it in front of the slit of the lantern, and we have the cyanin absorption spectrum on the screen. Now I have told you that when bromide of silver or iodide of silver is exposed to light, one atom of iodine or bromine is given off, and if the exposure be prolonged the amount is measurable, therefore it is possible that the bleaching action in the blue might be due to the action of bromine, and if so, bromine ought to be able to bleach cyanin blue. If we take bromine water and drop it into the cell, I think you will find that the whole spectrum will appear again in its usual brilliancy; we drop the bromine water in, and the whole spectrum does appear on the screen. Our question then is answered. The bromine liberated from the bromide of silver by the action of light when the dyed film was placed in the spectrum, was able to bleach it in the blue part of the spectrum in the same way that the oxygen in the air was able to bleach it under the influence of the yellow rays.

Now I will show you what the action of oxidised matter on silver is. Here we have a glass plate on which was written "May 25th" with an oxidised solution of albumen. This was coated with a collodion film containing bromide and iodide of silver, and developed in the usual way. You will see that where the oxidisable matter is placed, there we have a deposition of silver upon those particular portions. Apply this to the spectrum developed on a plate stained with cyanin blue; where it is bleached in the yellow, the oxidised dye will cause a deposit of silver to be formed,[1] whilst where the blue rays have acted we shall have a deposition of silver due to ordinary development, as already explained. I throw upon the screen a spectrum showing this. The film of collodion containing the silver salts was dyed, and then the bromide of silver dissolved away. You see we have a bleaching in the yellow and also a bleaching in the blue, one being due to the oxidising action of the yellow rays on the plate, the other due to the action of the bromine upon the dye itself. Next I will show you a photograph (No. IV. Fig. 5) of the spectrum taken on such a dyed plate. We have the part impressed by the blue rays, and a deposition of silver as before, and also we have the yellow where there is another strong deposition of silver. For convenience' sake I have photographed the absorption spectrum of cyanine and placed it below the spectrum photographed on the silver stained with cyanin. You will thus see that the band in the yellow impressed on the latter plate corresponds exactly with the absorption of the cyanin blue itself.

Carrying the investigation a little further, it was found that the same took place with eosin. I have an eosin solution here, and here is an absorption-spectrum of eosin which cuts off a great deal of the green—we have the yellow, but the green is cut out and the blue is damped. The green is the principal portion which is absorbed; in other words, the work which has to be done on the dye will be done in that part of the spectrum. In the photograph of the spectrum of eosin taken with bromide of silver dyed with eosin, you see as a result that we have the plate impressed by the blue rays, and also the plate impressed by the green. The deposition of silver on the two parts is due to different causes: that in the green is due to the work done on the dye; the work was not done on the silver directly, but on the dye first. That on the blue was due to the work done on the silver bromide itself. I may say that all dyes which I have found useful in the photographic sense are what we call fugitive dyes; in other words, dyes which fade in the light. Ladies are perfectly well acquainted with the fact that some dyes will not stand well; those which fade most rapidly give the best results in spectrum photography.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Clothworkers' Exhibition for proficiency in Physical Science, tenable for three years by an unattached student at Oxford or Cambridge, has been awarded to J. Davies. The next Clothworkers' Exhibition will be awarded for Physical Science by means of the examination for certificates to be held next July by the Oxford and Cambridge Schools Examination Board. Candidates must be non-collegiate students of one term's standing at Oxford or Cambridge, or non-residents who are prepared to enter as such.

The oral and practical examinations in the second part of the Natural Sciences Tripos concluded on Monday last (12th).

Prof. Stuart has now thirty-eight pupils in mechanism and engineering, and more space and new machinery are needed to meet their growing requirements. A new room measuring thirty-six by twenty-five feet is asked for, with motive power, a heavy lathe, a slotting machine and larger forge. Messrs. Greenwood and Batley will present a slotting machine when there is a place to put it in. The building will cost 225*l*.

Mr. D. MacAlister, Fellow and Medical Lecturer of St. John's College, will lecture on Methods of Physical Diagnosis three times a week next term, beginning February 2.

SOCIETIES AND ACADEMIES

LONDON

Linnean Society, December 3.—Sir John Lubbock, Bart., president, in the chair.—Mr. J. Harris Stone exhibited specimens of the dried plant and made remarks on *Lychnis viscaria* as a

[1] It has been objected by Dr. Vogel that the bleaching action requires time to effect it, and that the phenomenon is visible after a short exposure. The simple answer to the question is, When does the bleaching commence? The merest trace of reduced dye would act as a nucleus for development, as does the merest immeasurable trace of subiodide or bromide.

trap for ants. He pointed out that three or four glutinous or sticky rings are situate immediately underneath the nodes in the flowering stalks. Ants climbing the stems are arrested and die in numbers at the sticky zones, and few reach the flower. In Norway last summer he had observed as many as 95 per cent. of the plants with dead and dying ants thereon; and he therefore submits whether the zones are a protection to the flowers? the ants noxious? or that their dead bodies ultimately serve as pabulum for the plant? Dr. T. S. Cobbold exhibited diseased roots of *Stephanotus* which he had received from Dr. Masters. They swarmed with myriads of nematode worms and were also covered with minute Acari. He referred the worms to the genus *Leptodera*, and stated that thirty-three years back he discovered similar parasites in the shrivelled leaves of Gloxinias.—Dr. Maxwell Masters read a note on the foliation and ramification of *Buddleia auriculata*. He shows from a study of the mode of development and other considerations that the leafy auricles between the petioles represent leaves of a whorl, so that the verticil consists of two perfect and two imperfect leaves. An additional link between Loganiaceæ and Rubiaceæ is thus afforded. Further details were given concerning the multiple axillary buds in this plant and the supra-axillary shoots. Some of the peculiarities alluded to are usually explained on the hypothesis of fusion, but the author shows that in this, as in many similar cases, the appearances are due to an arrest of development, in consequence of which parts that should become free in course of growth remain inseparate, and in some cases are "uplifted" with the axis as it lengthens, and are thus removed from their normal position.—Prof. Owen read a paper on the homology of the conario-hypophysial tract, or the so-called pineal and pituitary glands. He propounds the view that it is the modified homologue of the mouth and gullet of Invertebrates; that the sub-œsophageal ganglia or ganglionic masses or neural cords constitute the centres whence are derived and caudally continued the homologues of the Vertebrate myelon.—Mr. McLachlan communicated a paper on the Neuroptera of Madeira and the Canary Islands. Prompted by the researches of the Rev. A. E. Eaton in November and December, 1880. The author gives a *résumé* of all that had been published on the subject, and a tabular statement of the species found in the islands, indicating those known also to exist in Europe. In all about 53 species had been noticed from the islands, of which 19 are known inhabitants of the European continent, and 4 African; 37 species had been found in Madeira, 31 in the Canaries, 16 being common to both. The paper concluded with a detailed account of the species, including descriptions of several new ones.—The following gentlemen were balloted for, and elected Fellows of the Society:—Capt. P. Greene, G. S. Jenman, W. Landau, E. G. Warnford Lock, Rev. T. P. H. Sturges, Lieut.-Col. C. Swinhoe, G. C. Walton, C. S. Wilkinson, G. S. V. Wills, and Rev. Geo. Wilson.

Mathematical Society, December 8.—Mr. S. Roberts, F.R.S., president, in the chair.—Mr. G. H. Stuart, M.A., late Fellow of Emmanuel College, Cambridge, was elected a Member, and Miss C. A. Scott was admitted into the Society.—The following papers were read:—On the polar planes of four quadrics, Mr. W. Spottiswoode, Pres. R.S.—On some forms of cubic determinants, Mr. R. F. Scott.—On the flow of a viscous fluid through a pipe or channel, Prof. Greenhill.—The covariant which is the complete locus of the vertex of the involution pencil of tangents to a cubic, Mr. J. J. Walker.

Chemical Society, December 1.—Prof. Roscoe, president, in the chair.—The following papers were read:—Researches on the laws of substitution in the naphthalene series, Part ii., by Dr. Armstrong and Mr. Graham. The product of the action of cold sulphuric acid on β naphthol proves not to be identical with the isomeric sulphonic acid of Rumpf, but to be β naphthyl-sulphonate. The same substance may be obtained pure by the action of sulphochloride on β naphthol. By studying the reactions of this body the authors prove that bromine and the sulpho group do not assume the same position in the body when the sulphate is treated with bromine and sulphochloride respectively, and express the opinion that modifications of the OH group appear to lead to important modifications of the laws of substitution. A third and a fourth isomeric naphthalene-disulphonic acid have been obtained.—On benzylphenol and its derivatives, by E. H. Rennie. The author has obtained a monosulphonic acid and its salts in a crystalline condition. He has investigated the action of nitric acid and of bromine on the salts. He believes benzolphenol to be a para derivative.—Note on the action of ethyli chlorocarbonate on benzene in the presence of aluminic chloride, by E. H. Rennie.—On peppermint camphor and some of its derivatives, by R. W. Atkinson and H. Yoshida. The authors have studied the action of bichromate on this camphor. Menthone is produced; from its reactions the authors conclude that the relation between menthol and menthone is similar to that between borneol and camphor. They have examined the physical properties of these derivatives, and give the probable constitution of these bodies.—On the production of oxalic acid from paraffin oil, by J. Galletly and J. S. Thomson. The authors have acted on paraffin oil from shale, with nitric acid, and find that oxalic acid is produced.

Physical Society, November 26.—Prof. W. G. Adams in the chair.—Mr. C. Vernon Boys read a paper on integrating apparatus. After referring to his original "cart" machine for integrating, described at a former meeting of the Society, he showed how he had been led to construct the new machine exhibited, in which a cylinder is caused to reciprocate longitudinally in contact with a disk, and give the integral by its rotation. Integrators were of three kinds: (1) radius machines, (2) cosine machines, (3) tangent machines. Sliding friction and inertia render the first two kinds unsuitable where there are delicate forces or rapid variations in the function to be integrated. Tangent machines depend on pure rolling, and the inertia and friction are inappreciable. They are therefore more practical than the other sort. It is to this class that Mr. Boys' machines belong. The author then described a theoretical tangent integrator depending on the mutual rolling of two smoke rings, and showed how the steering of a bicycle or wheelbarrow could be applied to integrate directly with a cylinder either the quotient or product of two functions. If the tangent wheel is turned through a right angle at starting, the machine will integrate a reciprocal, or it can be made to integrate functions by an inverse process. If instead of a cylinder some other surface of revolution is employed as an integrating surface, then special integrations can be effected. He showed a polar planimeter, in which the integrating surface is a sphere. A special use of these integrators is for finding the total work done by a fluid pressure-reciprocating engine. The difference of pressure on the two sides of the piston determines the tangent of the inclination of the tangent wheel which runs on the integrating cylinder, while the motion of the latter is made to keep time with that of the piston. In this case the number of revolutions of the cylinder measures the total amount of work done by the engine. The disk cylinder integrator may also be applied to find the total amount of work transmitted by shafting or belting from one part of a factory to another. An electric current meter may be made by giving inclination to the disk, which is for this purpose made exceedingly small and delicate, by means of a heavy magnetic needle deflected by the current. This, like Edison's, is a direction meter, but a meter in which no regard is paid to the direction of the current can be made by help of an iron armature of such a shape that the force with which it is attracted to fill the space between the poles of an electromagnet is inversely as its displacement, and then, by resisting this motion by a spring or a pendulum, the movement is proportional to the current, and a tangent wheel actuated by this movement causes the reciprocating cylinder on which it runs to integrate the current strength. Mr. Boys exhibited two such electric-energy meters, that is, machines which integrate the product of the current strength by the difference of potential between two points with respect to time. In these the main current is made to pass through a pair of concentric solenoids, and in the annular space between these is hung a solenoid, the upper half of which is wound in the opposite direction to the lower half. By the use of what Mr. Boys calls "induction traps" of iron, the magnetic force is confined to a small portion of the suspended solenoid, and by this means the force is independent of the position. The solenoid is hung to one end of a beam, and its motion is resisted by a pendulum weight, by which the energy meters may be regulated like clocks to give standard measure. The beam carries the tangent wheels, and the rotation of the cylinder gives the energy expended in foot pounds or other measure. The use of an equal number of turns in opposite directions on the movable solenoid causes the instrument to be uninfluenced by external magnetic forces. Mr. Boys showed on the screen an image of an electric arc, and by its side was a spot of light whose position indicated the energy and showed every flicker of the light and fluctuation of current in the arc. He showed on the screen that if the poles are brought too near the energy expended is less, though the current is stronger, and that if the poles are too far apart, though

the electromotive force is greater, the energy is less; so that the apparatus may be made to find the distance at which the greatest energy, and so the greatest heat and light, may be produced.—At the conclusion of the paper Prof. W. G. Adams and Prof. G. C. Foster could not refrain from expressing their high admiration of the ingenious and able manner in which Mr. Boys had developed the subject.

December 10.—Prof. W. G. Adams in the chair.—New members: Lieut. C. E. Gladstone, R.N., Lieut. C. Gauntlett Dicken, R.N., Mr. Walter George Woolcombe, B.A., F.L.S., Rev. Prof. Sircomb, Mr. Arthur Clayden, M.A.—Prof. Adams said that it had been thought advisable to invite the members to view the Smoke Abatement Exhibition now opened, and the meeting was adjourned for that purpose; Prof. Chandler Roberts acting as guide.—The next meeting of the Society will be held on January 28.

Paris

Academy of Sciences, December 5.—M. Wurtz in the chair.—The first volume of the works of Cauchy, the first of a new edition of the works of Niels-Henrik Abel, and the scientific MSS. of Chasles, were presented and commented upon.—General survey map of France, by M. Perrier. This is a work of the geographical service of the War Department, and indicates, by curves, the orography of the country.—Meridian observations of small planets and of comet *b* of 1881 at Paris Observatory, during the third quarter of 1881, by M. Mouchez.—On the theory of chain-shot, by M. Resal.—On some applications of the theory of elliptic functions, by M. Hermite.—Chemical studies on the skeleton of plants, by MM. Fremy and Urbain. The substances forming the skeleton are chiefly pectose and its derivatives, cellulosic substances in their different isomeric states, cutose, and vasculose. The results of analyses of stems, roots, leaves, petals, fruits, and seeds, also of the tissues of champignons, are given. It is thought they may be useful to botanists for classification, for physiological studies, for study of manures, and fossil fuel, &c., and that they have also industrial uses.—Summary account of a zoological exploration in the Atlantic, in the *Travailleur*, by M. Alph. Milne-Edwards. This exploration was chiefly off the coasts of Spain and Portugal, in August. In one case dredging was done at the great depth of 5100 m., where numerous animals were met with, small indeed, but of high groups (annelids, crustaceans, &c.); the temperature was $+3^{\circ}\cdot5$. Near the Spanish coast, and beyond 1000 m. depth, numerous polypiers, mostly unknown, showed marvellous development at some points. Among other "finds" were three very rare sharks (at 1200m.), which seem never to leave the depths, a Norwegian Pontophile, which had been thought peculiar to northern seas, a new Pontophile, a gigantic Pycnogonidian, ten new genera of Bryozoa, magnificent corals of the genera *Lophohelia* and *Amphihelia*, a remarkable *Asteria* representing a new genus, an organism got at 1145m., which may belong to the group of Infusoria, and (there also) a fine *Eugliphus* like *Difflugies* of fresh water.—On certain meteorological stations it is proposed to establish in the neighbourhood of the North Pole, by M. Faye. He thinks little of the project. Its authors consider that the ice of polar regions is *perhaps* the regulator of our climates; but modern science shows the regulator to be rather in the vast equatorial zone, whence storms travel over the two hemispheres. After expounding his conception of these phenomena, Mr. Faye points out that France would do better to organise a meteorological station in the Azores rather than at Cape Horn.—On the theory of linear differential equations of the second order, by M. Brioschi.—Deposit of metallic layers of different colours by electricity, by M. Weil. Using a single copper bath, he can cover steel or brass *e.g.* with bright layers of such and such a colour at will, by means of different suboxides of copper, whose chemical nature is not yet determined. The same bath will produce the whole series of colours according to the manner of exposing the pieces. The effect is not one of thin plates.—Observations in 1881 on phylloxera and on the means of defence adopted, by M. Boiteau.—Observations of solar spots and faculæ at the Observatory of the Roman College during the third quarter of 1881, by M. Tacchini. An exceptional *maximum* of spots occurred in July (as predicted). The solar activity has gone on increasing, with special periods of greater frequency of spots, nearly corresponding, as before, to a half-solar rotation. The faculæ show a marked maximum in September.—On the spectrum of Encke's comet, by M. Tacchini. This, observed on November 8, had the three carbon bands (the central brightest) shaded off on the violet side; the weak continuous spectrum of the nucleus forming a uniform straight line across the bands.—On Wendell's comet (*g* 1881), by M. Tacchini.—Rectification and addition to a previous note on the curve of the solar spots, by M. Duponchel. He predicts that the next sun-spot maximum will not be before 1890 (others say 1882), perhaps 1888, but more probably 1892.—On the curves defined by differential equations, by M. Poincaré.—Distribution of energy by electricity, by M. Deprez.—On the determination of the ohm; reply to M. Brillouin, by M. Lippmann.—Variations of the resistance of electric machines with their velocity, by M. Lacoine. He shows reason for thinking these variations are explained by those of contact between the movable commutator and the springs in friction.—Determination of the illuminating power of simple radiations, by MM. Crova and Lagarde. Sunlight and a Carcel lamp were compared. Part of the spectrum is isolated with a slit, and a Nicol turned till striæ cease to be perceptible. With the lamp the maximum corresponds to the radiation 592; with the sun, to 564.—On the velocity of cooling of gases at high temperatures, by MM. Maillard and Le Chatelier.—Combination of hydrogen with oxygen under the influence of electric *effluves*, by MM. Deherain and Maquenne. The state of humidity of the surfaces between which the *effluve* is produced affects profoundly the nature of the discharge, both as to external aspect, and to its action on the gases.—On the titrage of œnoline and œnotannin in wines, by M. Jean.—Meteorological observations during a balloon ascent on October 20, 1881, by MM. Duté, Poitevin, and Du Havel. These relate chiefly to formation of clouds.—Observation of palpebral reflex in chloroformic anæsthesia, by M. Berger.—On the convulsing action of morphine in mammalia, by MM. Grasset and Amblard. All researches on the antagonism of various medicaments to morphine should be revised, the substances opposing the soporific effects, and those opposing the excito-motor effects of the alkaloid, being studied separately.—Researches on the history of generation in insects, by M. Jobert.—On the post-embryonal development of diptera, by M. Viallanes.—Researches on the action of digestive juices of cephalopoda on amylaceous matters, by M. Bourquelot. The liver and pancreas produce or contain a ferment which has no action on raw fecula, but which changes hydrated starch into sugar.—On the diamantiferous beds of Minas Geraës, Brazil, by M. Gorecix.—M. De Lesseps gave some information with regard to the scheme for piercing the Isthmus of Corinth.

Vienna

Imperial Academy of Sciences, December 1.—V. Burg in the chair.—The following papers were read:—R. Andreasch, on some further examples of syntheses of the sulphydantoins by means of thioglycollic acid.—Anton Tomaschek, on the power of movement of pollen-bags and pollen-tubes.—W. F. Loebisch and Dr. A. Looss, on the action of carbonic oxide gas on monopotassium glycerate.—On the preparation of dipotassium glycerate, by the same.—T. Hann, on the monthly and yearly oscillations of temperature in Austro-Hungary.

THURSDAY, DECEMBER 22, 1881

ARCTIC SUCCESS AND DISASTER

THIS has been a stirring Arctic week. First we have the publication of one of the most remarkable narratives of one of the most successful Arctic voyages ever made, to which we refer in detail on another page. On Tuesday an influential deputation waited on the Earl of Northbrook, to urge upon Government the necessity of sending out an expedition to succour Mr. Leigh Smith in the *Eira*. And, also, on the same day, the wires which about two years ago transmitted the welcome news of the safety of Nordenskjöld's expedition in the *Vega*, and the successful navigation of the North-east Passage, bore to Europe the sad news of disaster to the *Jeannette*. Sad though the news be, it is not nearly so bad as was to be feared, for we doubt if many besides Mr. Gordon Bennett had any faith in the survival of the expedition, and the search parties that were to be sent out next spring were generally looked on as forlorn hopes. From the news which has been transmitted from Yakutsk to St. Petersburg, and thence to London and Paris, it is not quite easy to make out the details. The following extract is from the telegram of the St. Petersburg *New York Herald* correspondent to the Paris office of that paper; he quotes from a telegram to General Ignatieff, dated Irkutsk, December 19:—

"The Governor of Jakutsk writes that on September 14 three natives of Hagau Oulouss de Zigane, at Cape Barhay, 140 versts north of Cape Bikoff, discovered a large boat, with eleven survivors from the shipwrecked steamer *Jeannette*, who had suffered greatly. The adjunct of the chief of the district was immediately charged to proceed with a doctor and medicines to succour the survivors at Jakutsk and to search for the rest of the shipwrecked crew. Five hundred roubles have been assigned to meet the most urgent expenses. The engineer, Melville, has sent three identical telegrams, one addressed to the London office of the *Herald*, one to the Secretary of the Navy at Washington, the third to the Minister of the United States at St. Petersburg. The poor fellows have lost everything. Engineer Melville says that the *Jeannette* was caught and crushed by the ice on June 23, in latitude 77 and 157 east longitude. The survivors of the *Jeannette* left in three boats fifty miles from the mouth of the Lena. They lost sight of each other during a violent gale and dense fog. Boat No. 3, under command of Melville, having reached the eastern mouth of the Lena on September 29, was stopped by icebergs near to the hamlet of Idolaciro Idolatre on October 29. There also arrived at Bolonenga boat No. 1, with the sailors Hindmann and Hoross, with the information that Lieut. de Long, Dr. Ambler, and a dozen other survivors had landed at the northern mouth of the Lena, where they are at present in a most distressing state, many having limbs frozen. An expedition was immediately sent from Bolonenga to make diligent search for the unfortunates in danger of death."

From this and from the Reuter's telegram it would seem that Boat No. 1 has not yet turned up. The spot where the disaster overtook the *Jeannette* is a short distance east of the most easterly of the New Siberian Islands. The exact spots where the boats landed are not quite clear, and probably there has been some misspelling of names; but it is evident that it is somewhere on the complicated delta of the Lena. It will be remembered that the *Jeannette*, the old *Pandora*, was sent out two and a half years ago by Mr. Gordon Bennett, for Arctic exploration by the Behring Straits route. It now appears that Mr. Bennett's instructions were that the ship should keep by the east side of Siberia, and embrace the first favourable opportunity of making for the Pole. These instructions her Commander, Capt. De Long, had evidently been doing his best to carry out. She was last seen in September, 1879, when she was steering north-east from Wrangel Land. Probably she has run round the north side of the Island, and attempting the north-west route been caught in the drift like the *Tegetthoff*, and finally crushed. The sufferings of the unfortunate explorers must excite universal pity, though all will rejoice that it has not come to the worst with them. The route they took was a perfectly new one, and it is possible they may have something new and important to tell us. The expedition was in some respects of the old-fashioned kind, rushing blindly into regions about which absolutely nothing was known; but this is how all knowledge has been purchased. Still, had something of the scientific method of Baron Nordenskjöld been adopted, the result might have been different. Further news of the shattered but so far saved expedition will be anxiously looked for; they will have an exciting and terrible story to tell, but we trust that their sufferings will prove not barren of results to science. If they have established the existence of a line of islands to the north of the New Siberian Islands, one more of the Arctic problems will have been solved.

In view of this disaster, no doubt it will be a relief to many to learn that Lord Northbrook's reply to the deputation from the Geographical Society was quite favourable and that probably a relief expedition will be sent out for the *Eira*. At the same time we believe a Government expedition, however much Mr. Leigh Smith deserves, such attention, was not necessary; and we doubt much if Mr. Leigh Smith's relatives were not rather surprised when it was suggested to them that they should petition for Government assistance. Now that the search expedition is virtually decided on we wish it every success, at the same time hoping that it will be strictly confined to its ostensible purpose. To Government Arctic explorations we are certainly favourable; but we trust that the next expedition sent out will be constituted and organized on as thorough a scientific method as that in the *Vega*; and that, as in the *Vega*, there will not only be a special scientific staff, but that the real commander of the expedition, subject to contingencies of navigation, will be a man with the scientific training and methods of Baron Nordenskjöld. In short, let the staff consist of men trained in the various departments of science, and not primed in haste for the occasion.

The unfortunate disaster to the *Jeannette* will no more check Arctic exploration than many another greater disaster that has marked the progress of knowledge; it can only be hoped, while expressing our genuine sympathy with the sufferers, that Arctic explorers will learn from it all the lessons it ought to teach.

CHARLES LYELL[1]

Life, Letters, and Journals of Sir Charles Lyell, Bart., Author of the Principles of Geology, &c. Edited by his Sister-in-law, Mrs. Lyell. In two volumes. With Portraits. (London: John Murray, Albemarle Street, 1881.)

II.

In our previous notice of this work we have dwelt at some length upon the insight which it affords us concerning the origin and history of the book, which constitutes Lyell's chief title to fame. But the fact must not be lost sight of that, besides writing the "Principles of Geology," Lyell gave to the world a number of other books and original memoirs of the highest scientific value, though their fame has been overshadowed, to some extent, by that of his great work. The "Principles of Geology" was not, as some would have us suppose, a mere compilation from the works of other authors, for in every page of it we find embodied the results arrived at by the author after careful personal observation and close reasoning. Lyell, in a letter addressed to Edward Forbes, in 1846, very properly protests against the idea that original observations and theories are only to be published in journals of science and the proceedings of learned societies. He says:—

"On the Continent I gain no priority for any original views or facts which have only appeared in my 'Principles' and 'Elements.' When the Geological Society of France voted a sum of money to Archaic to draw up a report on the progress of geology for ten years (1835 to 1845, I believe), he wrote to me to say that all treatises on geology were left out of such reports, as they were presumed to be compilations, authors taking care to take date for their discoveries in scientific journals, but as my book was an exception to such rules, he wished me to send him an exact list of all my original theories and facts, and their dates, which, owing to their numerous editions, no one could make out, and which he must neglect without such aid" (vol ii. p. 107).

Among the new observations and generalisations to which Lyell may justly lay claim, we will here allude to one only. Before the appearance of the "Principles of Geology" no serious attempt had been made to bring into correlation those important deposits which overlie the chalk, which the labours of the Italian and French naturalists had invested with so much interest. William Smith's classification of strata, which had met with very general acceptance, both in England and on the Continent, dealt with the formation from the Carboniferous to the Cretaceous inclusive. But above and below those limits the greatest confusion and doubt existed in connection with all questions of geological classification.

What Sedgwick, Murchison, and Lonsdale did for the pre-Carboniferous rocks, Lyell accomplished single-handed for the post-Cretaceous; and his classification, though the advance of knowledge has necessitated modifications in it, is at the present day universally accepted so far as its main features are concerned. The amount of work undertaken by Lyell in collecting the facts upon which this Tertiary Classification is based was enormous, and is well set forth in the volumes before us (vol. i. pp. 182–319).

Besides the "Principles of Geology" and the expansions of the last part of that work, published under the successive titles of "The Elements of Geology," "A Manual of Geology," and "The Student's Elements of Geology," Lyell wrote four volumes of "Travels in North America," teeming with original facts and observations, and his "Antiquity of Man," or as the *Saturday Review* called it, "Lyell's Trilogy on the Antiquity of Man, Ice, and Darwin." And in addition to these separate works nearly seventy original memoirs contributed to scientific journals are recorded in the list at the end of the work lying before us, besides reviews, lectures, and addresses.

In obtaining the materials for these multitudinous publications Lyell was a most indefatigable worker. Every year he spent a number of months in travelling over parts of Europe or his own country, examining for himself the districts of which he had to treat in his works. It was very characteristic of Lyell that, though willing to learn from the youngest of his contemporaries, he never took anything on trust where personal examination was possible; and it was rarely indeed that his acute powers of observation and logical mind failed to extend, improve and correct the results attained by previous workers in the same field. He visited North America four times, spending thirteen months on his first tour, and nine months on his second, and subsequently resided for some months at Madeira.

But it is not only on account of the record which they contain of Lyell's own work, that the volumes before us are of such great value. Lyell was an active participator in all the scientific movements of his day, and his account of the meetings of the Geological Society, with its stormy debates, of the Geological Club and its convivial gatherings, of the Royal Society and the British Association, are full of the most lively and interesting details. Concerning a debate at the Geological Society in 1829 he writes to Mantell:—

"The last discharge of Conybeare's artillery, served by the great Oxford engineer against the Fluvialists, as they are pleased to term us, drew upon them on Friday a sharp volley of musketry from all sides, and such a broadside at the *finale* from Sedgwick, as was enough to sink the 'Reliquiæ Diluvianæ' for ever, and make the second volume shy of venturing out to sea. After the memoir on the importance of all rivers which feed the 'main river of an isle,' and the sluggishness of Father Thames himself 'scarce able to move a pin's head,' a notice of Cully, land-surveyor, was read on the prodigious force of a Cheviot stream, 'the College,' which has swept away a bridge and annually buries large tracts under gravel. Buckland then jumped up, like a counsel, said Fitton to me, *who had come down special.*"

"After his reiteration of Conybeare's arguments, Fitton made a somewhat laboured speech. I followed, and then Sedgwick, who decided on four or *more* deluges, and said the simultaneousness was disproved for ever, &c., and declared that on the nature of such floods we should at present 'doubt and not dogmatise.' A good meeting" (vol. i. p. 253).

Here is his account of the anniversary meeting of the Geological Society in the same year:—

"Sedgwick quite astonished them, it seems, in the chair at the general meeting, which was very full. Among innumerable good hits, when proposing the toast of the Astronomical Society, and Herschel, their president, he said, alluding to H.'s intended marriage (for he is just about to marry the daughter of a Scotch clergyman),

[1] Continued from p 148.

'May the house of Herschel be perpetuated and, like the Cassinis, be illustrious astronomers for three generations. May all the constellations wait upon him! may Virgo go before, and Gemini follow after!' Poor H., notwithstanding his confusion, got up after a roar of laughter had continued for three minutes, and made a famous speech" (vol. i. 251).

In the whole of these letters of Lyell there is a striking absence of anything like jealousy or ill-nature in his remarks. His judgment concerning his contemporaries, whom he had the greatest facilities for knowing, appears to be remarkably just and such as will, we believe, be endorsed by posterity. Take for example what he says concerning the great rivals Murchison and Sedgwick:—

Murchison "has a little too much of what Mathews used to ridicule in his slang as 'the keep-moving, go-if-it-kill-you' system, and I had to fight sometimes for the sake of geology, as his wife had for her strength, to make him proceed with somewhat less precipitation" (vol. i. p. 107).

"Murchison is one who has worked at science chiefly for the rewards, but not entirely, for if he had had no pleasure in it he would have failed; Sedgwick and Conybeare for the pleasure chiefly. What I shall always cherish, is a love for science, rather than its rewards; but I indulge the hope of profit, as the best earnest of usefulness, and also against its becoming a duty to accept some offer of an uncongenial situation" (vol. i. p. 373).

"Sedgwick asked me to walk home with him. I found a gloom upon him, unusual and marked. I most carefully avoided all allusion to the rejected living, but now when the first excitement of declining the boon is over, and that others have expressed their wonder at it, and that he finds himself left alone with his glory, he is dejected. He told me, Thursday last, that he wished before he left Cambridge, to *do something*. 'Now if I take a living instead of going to Wales, I abandon my professorship, and cannot get out the volume on the primary rocks with Conybeare,' &c. Then he hinted that in a year, when this is done, he may retire on some living, and *marry*. But I know Sedgwick well enough to feel sure that the work won't be done in a year, nor perhaps in two; and then a living, &c., won't be just ready, and he is growing older. He has not the application necessary to make his splendid abilities tell in a work. Besides every one leads him astray. A man should have some severity of character, and be able to refuse invitations, &c. The fact is, to become great in science, a man must be nearly as devoted as a lawyer, and must have more than mere talent" (vol. i. p. 375).

With respect to the unfortunate quarrel between these two pioneers in the study of the older palæozoic rocks, the line which Lyell adopts appears to us to be singularly just and judicious. He could not but see that Sedgwick's wrongs, like his maladies, were to a great extent imaginary, and, doing so, was filled with regret at the folly which made so able a man nurse his mortification and rage till it embittered the whole of his subsequent life. Writing in 1855 Lyell says:—

"In Phillips's new edition of his 'Geology,' just out, he makes the Lingula beds Cambrian, just as I do, which I am glad of, as however Murchison may complain, it is really we that are adhering to the original divisions and names adopted by Murchison and Sedgwick. It would be wrong to give up the term Cambrian just when we are beginning to have a distinct fauna for it, as Salter was the first to show here, and Barrande in Bohemia. Sedgwick's attempt to take the Lower Silurian into his Cambrian is even worse than Murchison claiming all that is older than the Devonian as appertaining to his Silurian" (vol. ii. p. 205-6).

Lyell had great opportunities of knowing Cuvier, and we cannot refrain from quoting what he tells us about the great naturalist's method of organising his work:—

"I got into Cuvier's *sanctum sanctorum* yesterday, and it is truly characteristic of the man. In every part it displays that extraordinary power of methodising which is the grand secret of the prodigious feats which he performs annually without appearing to give himself the least trouble. But before I introduce you to this study, I should tell you that there is first the Museum of Natural History opposite his house, and admirably arranged by himself, then the Anatomy Museum connected with his dwelling. In the latter is a library disposed in a suite of rooms, each containing works on one subject. There is one where there are all the works on ornithology, in another room all on ichthyology, in another osteology, in another *law* books! &c., &c. When he is engaged in such works as require continual reference to a variety of authors, he has a stove shifted into one of these rooms, in which everything on that subject is systematically arranged, so that in the same work he often takes the round of many apartments. But the ordinary studio contains no bookshelves. It is a longish room comfortably furnished, lighted from above, and furnished with eleven desks to stand to, and two low tables, like a public office for so many clerks. But all is for the one man, who multiplies himself as author, and admitting no one into this room, moves as he finds necessary, or as fancy inclines him, from one occupation to another. Each desk is furnished with a complete establishment of inkstand, pens, &c., pins to pin MSS. together, the works immediately in reading and the MS. in hand, and in shelves behind all the MS. of the same work. There is a separate bell to several desks. The *collaborateurs* are not numerous, but always chosen well. They save him every mechanical labour, find references, &c., are rarely admitted to the study, receive orders, and speak not."

"Brongniart, who, in imitation of Cuvier has many clerks and collaborateurs, is known to lose more time in organising this auxiliary force than he gains by their work, but this is never the case with Cuvier. When I went to get Mantell's casts I found that the man who made moulds, and the painter of them, had distinct apartments, so that there was no confusion, and the despatch with which all was executed was admirable. It cost Cuvier a word only" (vol. i. p. 249).

Although Lyell devoted all his energies to the advancement of geological science, and, as his letters show, steadfastly refused all honours and engagements which would interfere with the performance of the great tasks he had set before himself, yet he was far from being a recluse or one refusing to take an interest in the affairs of the time. His earliest essays in the *Quarterly* were employed in the advocacy of the importance of giving scientific instruction in schools and universities. In his "Travels in North America" he devoted a chapter to the subject of University Reform, and his remarks produced a great impression at the time, and before the Public Schools Commission he gave important evidence. In the reform of the Royal Society he was one of the most active members, and in many of the great movements of the day we find him playing the part of an earnest and advanced liberal.

On other than scientific subjects we may not stay to speak here, but we cannot refrain from mentioning that Lyell's works on America did much to dispel among the educated classes, on both sides of the Atlantic, the feeling

of irritation which had been aroused by the publication of the caricatures in Dickens' "American Notes" and "Martin Chuzzlewit." Non-scientific readers, too, will find much to interest them in these volumes, in the conversations and anecdotes of such men as Scott, Lockhart, Rogers, Whewell, Babbage, Macaulay, Sidney Smith, Milman, and many other eminent men with whom Lyell was on terms of close intimacy. The literary gossip is indeed scarcely less interesting than the scientific.

Of Lyell's amiable and gentle nature these letters and journals afford abundant and interesting evidence. His correspondence with his wife and sisters, and his little nephew, abound with illustrations of the beautiful traits of his character; and the warmth of his attachment comes out very strikingly in his communications with Mantell, Fleming, Horner, Darwin, and others, with whom he was in constant and friendly intercourse. His greatest weakness was perhaps the excessive caution, sometimes approaching timidity, which is exemplified very strikingly in his correspondence with Darwin and Hooker in vol. ii. pp. 361-366. But it must be remembered that it was this same cautious habit which first enabled him to gain the public ear, when it was but little disposed to attend to the teachings of science, and his reputation for this character gave to his later writings on scientific questions an authority which perhaps no other living writer could command. It was in consequence perhaps of this that Lyell's opinions on the subject of evolution, as stated in the "Antiquity of Man," were received by the public like the summing up of a judge, rather than as the speech of an advocate.

We cannot better conclude this notice of Lyell than by quoting the words of his friend the late Dean Stanley, on the occasion of the funeral sermon in Westminster Abbey:—

"Of him who is thus laid to rest, if of any one of our time, it may be said that he followed truth with a zeal as sanctified as ever fired the soul of a missionary, and with a humility as child-like as ever subdued the mind of a simple scholar. For discovering, confirming, or rectifying his conclusions, there was no journey too distant to undertake. Never did he think of his own fame or name in comparison with the scientific results which he sought to establish. From early youth to extreme old age it was to him a solemn religious duty to be incessantly learning, constantly growing, fearlessly correcting his own mistakes, always ready to receive and reproduce from others that which he had not in himself. Science and religion for him were not only not divorced, but were one and indivisible."

These words were spoken when the grave had but just closed over Lyell's mortal remains, but in the hearts of many who had the happiness of knowing and loving him, his memory will long continue green.

JOHN W. JUDD

OUR BOOK SHELF

A Treatise on the Diseases of the Nervous System. By James Ross, M.D. Two Vols. (London: Churchill and Co., 1881.)

THIS is a complete treatise on Diseases of the Nervous System, illustrated with lithographs, photographs, and many woodcuts, of which the latter have mostly been borrowed from several well-known anatomical and physiological works. The book is in many respects a valuable one, though in others it is not altogether satisfactory. The author is thoroughly accomplished in all that concerns the anatomy and physiology of the nervous system, and he is evidently fully impressed with the absolute importance of an adequate attention to details of this kind on the part of those who would master or keep themselves abreast of modern knowledge concerning disease of the nervous system. A vast amount of work has been done in strengthening our knowledge in this direction during recent years, and as a consequence in no department of medicine have greater advances in the direction of precision of diagnosis been arrived at. In no other work are these anatomical and physiological data, on which the practitioner must largely depend, so copiously reproduced. In this direction, indeed, there is some redundancy. Some of the chapters (such as Chap. I. of Vol. I.) might with advantage have been omitted altogether from the present work, whilst others (such as Chap. I. of Vol. II.), dealing with the Anatomy and Development of the Spinal Cord, might have been very considerably curtailed. An anatomical treatise is one thing, but a work on a department of practical medicine is another thing altogether, although in it many anatomical references ought to exist. On the physiological and pathlogical sides, what the author has to say concerning Inhibitory Functions generally, and concerning "Synkinesis" (or the pathology of Associated Movements), will be found to be both judicious and more or less original. But in studying the author's account of the special diseases of the nervous system, especially in the light of other previous and fuller disquisitions, one cannot help seeing that much of the work (as in the section on Paralysis of the Facial Nerve, for instance) partakes of the nature of careful compilation, and is defective in evidence that the author himself has had any very large experience of the diseases concerning which he treats. Some of the special diseases are indeed altogether inadequately discussed, considering the style of the work generally. In fine, this treatise, though not without considerable merits, is unequal and in many places over-diffuse in its treatment of different parts of the subject. Greater strength and evidence of a larger practical experience in dealing with the different nervous diseases would have made the book more evenly balanced, and caused the reader to think less of its redundancies. These blemishes might perhaps be rectified in a subsequent edition. At present it is a work which will probably possess more interest for the few who are already conversant with nervous diseases, than for the many medical men and students who desire to make themselves more acquainted with them. To the latter its bulk (about 1600 pages) will probably be alarming. The book ends with that most commendable thing, a good index.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Function of the Ears, or the Perception of Direction

REFERRING to the letter in NATURE (vol. xxv. p. 124) I may add that M. Buhler, our French landscape gardener, judges nicely the direction of sound. Some years ago I requested him to trace a walk across a wood so undergrown with a creeping plant that it was impossible to cross it. Having fixed the entrance and exit by going round the wood, he told my negro servant to answer every call of his by a shout. It just then occurred to me that an experiment might be made; and I ordered the negro (in his own language) not to shout, but to

whistle. As the ground was sloping, the walk was to be a curve; and Buhler, with little hesitation, pointed out the places where pegs should be laid by a man who opened a narrow path with a hatchet. Buhler did not retrace his steps, and left my grounds after saying that he had pegged the right side of a walk three metres broad. He then complained of the difficulty he had experienced because *that stupid darkie* had whistled in place of shouting. When the ground was cleared a few days afterwards, I found the curve even and seemingly faultless. When listening to each whistle Buhler turned his face, not towards it, but in the direction of the curve which must ultimately meet it. Have not English landscape gardeners the same faculty of judging rightly direction by sound ANTOINE D'ABBADIE

Abbadia, Hendaye, December 11

Dante and the Southern Cross

THE question "where Dante could have learned about this constellation" (*ante*, p. 152) has been discussed by most modern commentators on the passage referred to. The general conclusion arrived at seems to be that it was through the delineation of the "quattro stelle" on Arabian celestial globes. The best scientific discussion of the question will be found in Humboldt's *Kosmos* ii. 205, 6 (ed. 1870). Might not, however, the line "Non viste mai fuor ch' alla prima gente" suggest that Dante's knowledge was derived from some record or tradition, of the visibility of these and other southern stars to the inhabitants of the Mediterranean shores before the precession of the equinoxes carried them below their horizon? "Prima gente"—generally rendered "our first parents"—recalls irresistibly Horace's "prisca gens mortalium." J. J. WALKER

University Hall, December 18

YOUR correspondent who inquires whence Dante obtained his knowledge of the existence of the Southern Cross may be referred to Humboldt's travels for one explanation of this remarkable fact. I apprehend your correspondent alludes to the lines—

"To the right hand I turn'd and fix'd my mind
On the other pole attentive, where I saw
Four stars ne'er seen before save by the ken
Of our first parents. Heaven of their rays
Seem'd joyous. Oh thou northern site! bereft
Indeed, and widow'd, since of these deprived."

Dr. Barlow, the commentator of Dante, accepts Humboldt's explanation, and says: "The principal stars of this constellation were known when Dante wrote, and in the description here given there is a reality attested by all who have seen them. They were once visible in our northern hemisphere." Alexander von Humboldt, from whose philosophic soul the poetry of nature was never absent, says of them:—"In consequence of the precession of the equinoxes, the starry heavens are continually changing their aspect from every portion of the earth's surface. The early races of mankind beheld in the far north the glorious constellations of the southern hemisphere rise before them, which, after remaining long invisible, will again appear in these latitudes after a lapse of thousands of years. The Southern Cross began to be invisible in 53° 30′ north latitude, 2900 years before our era, since, according to Galle, this constellation might previously have reached an altitude of more than 10°. When it disappeared from the horizon of the countries of the Baltic the great pyramid of Cheops had already been erected more than 500 years." Barlow therefore infers with Humboldt that Dante knew of the Southern Cross by tradition, and adds that the words our "first parents" do not refer to Adam and Eve, but to the early races which inhabited Europe and Asia.

Grosvenor Street SAMUEL WILKS

Helophyton Williamsonis

I AM sorry to see that I have overlooked two mistakes in my brief note which you published in your last number (p. 124). In the fifth line *Hymenophylloides* should have been *Myriophylloides*; and lower down Urrger should of course be Unger.

WM. C. WILLIAMSON

Victoria University, Manchester, December 9

A Smokeless London

IT is not very improbable that we shall in a few years be indebted to the electric light for our source of nightly illumination. Before such an eventuality it would be interesting to know if there are any serious objections to employing hydrogen gas as our heating agent. Smokeless and innocuous in combustion, it would relieve us from many ills under which we labour now. When it was tried—after impregnation with a hydrocarbon—as a lighting agent (at Chichester, I believe) some years ago, it was found wanting, but there was no difficulty, I think, experienced in producing it cheaply from the decomposition of water and in sending it through the mains. No notice, I believe, has been directed to this at the Smoke Abatement Exhibition. Will you kindly raise the issue, and let us know the advantage or disadvantage of the project? EDMUND MCCLURE

1, Onslow Place, S.W., December 16

Meteors

ON the evening of Wednesday, November 16, whilst sweeping the western heavens in search of comets, I was startled by a brilliant illumination to my right. Looking up hastily, a bright meteor was seen moving rapidly in the north-eastern heavens; it started about 3° north of Capella, and traversed a path of some 10° in a north-easterly direction, passing about 2° above (or west of) δ Aurigæ. Its flight did not exceed three seconds, when it burst with a dazzling brilliancy to be compared only to the whiteness of the electric light. At the moment of bursting, it must have been at least five or six times as bright as Venus at her maximum. It left in its wake, covering the full length of its path, a thin, reddish train, which drifted slowly toward the north-east among the stars, gradually collecting into a lightish cloud at its north-east end. Noting the remarkable permanency of the train, I turned the telescope (a 5 inch refractor) upon it, and was surprised to see a brightly-glowing mass of pinkish smoke. The same matter was stretched out toward the south-east into a long, straggling strip. This trail was about ½° in breadth, and could be plainly seen with the telescope for a distance of at least 10°. The whole of this drifted north-easterly over the stars, curling slowly like a mighty serpent; it was knotted in places with cumulus forms, probably due to minor explosions in the meteor. The outlines of this wonderful train of celestial smoke were well defined; it did not diffuse itself into the atmosphere, but gradually faded, becoming more contorted each moment. During the whole time of its visibility it retained its pinkish colour. The first appearance of the meteor was at 6h. 48m. local time; the train remained visible to the naked eye for about six minutes. In the telescope it was distinct up to seven o'clock, and at 7h. 03m. it could still be seen in the instrument. While visible, it drifted about 4° to the north-east. No explosion was heard, though listened for. Latitude of place of observation, 36° 10′ north; longitude west of Greenwich, 86° 49′. E. E. BARNARD

Nashville, Tennessee, U.S.A., November 27

ON Wednesday, December 14, at 10.30 p.m., I saw a very brilliant meteor. It appeared to start from the barren region of the Lynx, bordering on the Twins, a little to the east, and above Pollux, and travelled in the direction of Canis Minor. It was much brighter than any object then shining, though Jupiter and Sirius were both visible, and left a train of light behind which appeared to be granular, of a dull red colour, and fusiform in shape. I did not see the meteor through its entire path, on account of a house intervening, but the train of light behind it was not visible at the commencement of its path, and appeared to terminate before the disappearance of the meteor. This was by far the brightest meteor I ever saw. The same evening and the week previously I saw many meteors in the region of Aries, but none very brilliant. E. HOWARTH

Sheffield Museum and Observatory, December 18

Herbaceous Stem on a Palæolithic Implement

INSTANCES are so extremely rare where vegetable material (as old as the drift gravels) is found adherent to drift implements, that the following instance is probably worthy of note:—Amongst my collection of Palæolithic implements from the neighbourhood of Bedford, I have one *perfectly unabraded* example—bright ochreous yellow in colour from its long deposition in the drift. Near the middle of the implement there are the remains of some herbaceous stem firmly fixed to the flint; the colour of the vegetable material is bright ochreous, and under the microscope the vegetable structure (especially the vessels) is most clearly

seen; the patch is an inch long and about a quarter of an inch in average width; it has not the stellate cells of the rush. The material has been protected in a depression in one of the artificial facets of the implement, and in a second position somewhat nearer the butt, there is further trace of the same material. My opinion is that these grass stems (or whatever stems they may be) were possibly wrapped round the basal end of the implement as a protection for the hand against the asperities of the flint. The asperities are very noticeable in the instrument referred to, as it has a sharp cutting edge at the butt, with none of the original bark of the flint left for convenience of holding. The vegetable material is undoubtedly as old as the implement, and the unabraded condition of the stone may account for its position in the facets. WORTHINGTON G. SMITH

125, Grosvenor Road, Highbury, N.

Awned Carpels of Erodium

SIR JOHN LUBBOCK's address to the British Association, and Mr. Francis Darwin's paper in the Linnean *Transactions*, on the hygrometric awns of the achenes of *Erodium* and other plants, fail to give the honour to the right man. Their references reach some thirteen years back; but if they will look further they will find the late discoveries (including those of Hildebrand and Zimmerman in *Pringsheim's Jahrbücher*) forestalled as to *Erodium* by nearly half a century. In the *Magazine of Natural History* for 1836 is a modest contribution of nearly two pages from Robert Mallet of Capell Street, Dublin, describing and figuring his observations on the achenial awns of *Erodium moschatum* and *Pelargonium peltatum*. He finds that the awns of *Erodium* possess "most wonderful hygrometric sensibility." The five awns lie in grooves of the carpophore. He gives transverse views of the awns in various conditions of torsion, and of the carpophore (not as well executed as the similar ones of F. Darwin and Hildebrand). He states that aridity causes the awns to twist, and so to extricate themselves from their grooves, and at the same time downy filaments bristle forth from the awns, and the achenes detach themselves and fall to the ground. Here the awns still continue to twist and keep tumbling over, so as to recede from the parent plant. At last by twisting they become like balloons wafted about by every zephyr. But motive power has not ceased with the awn: the slighest hygrometric change produces motion either backwards or forwards in it; and the constant tendency of this motion is to *screw the seed into the ground* (Mr. Mallet's italics). Such is the shape and great sensibility of the awns, that they may be readily applied to form most delicate hygrometers, for which purpose he had used them. Nearly all of these observations have been rediscovered and confirmed and published in elaborate form by the eminent investigators of our own day.

Princeton College, November 15 G. MACLOSKIE

The Song of the Lizard

WHILST quartered in St. Helena, at Ladder Hill, I was frequently disturbed by the "*tweet-tweet*" of a small lizard in the verandah and Melia trees which overshadowed it, which sounds for a long time I thought were produced by birds. It is, according to Melliss' description, the "*Hemidactylus frenatus* (Schleg.).—A small brown harmless lizard about four inches in length, which lives under stones and old timber in the warm lower parts of the island. It seldom enters houses unless in pursuit of flies or scorpions, but is plentiful about the neighbourhood of Jamestown, where in the evening its loud chirp is frequently heard." This may corroborate Mr. Pascoe's remarks in his letter to NATURE (vol. xxv. p. 32). S. P. OLIVER

2, Eastern Villas, Anglesey, Gosport

A Double Egg

I HAVE received a very remarkable egg, or rather, I should say, a double egg, laid by a hen belonging to Mr. Isaac Sharman, of Kanmoor, Sheffield. The egg weighed 4¾ oz., and measured round its greatest circumference 8 inches, and its least 7 inches. In measuring the egg the shell was broken, and inside the outer shell there was no yoke but simply white of egg surrounding another perfect egg of the average size. This inner egg has the shell quite complete and hard. Mr. Sharman describes the bird as a cuckoo hen. E. HOWARTH

Sheffield Public Museum, December 12

SIR ANTONIO BRADY

IT is always with a keen feeling of regret that we record the loss from the scientific ranks of men whose faces, as well as their names, were familiar to us by long association, and who were for years fellow-workers in the same geological area. Such a one was Sir Antonio Brady, F.G.S., who passed from among us on the 12th inst. from an affection of the heart.

He was the eldest son of the late Mr. Anthony Brady, of the Royal William Victualling Yard, Plymouth, by his marriage with Marianne, daughter of Mr. Francis Perigal. Born in 1811 he entered the Civil Service of the Navy as a junior clerk in the Victualling Yard, Deptford, more than fifty years since. After serving in various offices, having been promoted to head-quarters, he became head of the Contract Office and Registrar of Public Securities in 1854, subsequently assisting to reorganise that office. After the reorganisation of the office he was appointed first superintendent of the Purchase and Contract Department, retiring from the service in 1870, when he received the honour of knighthood. Since his retirement from the public service, Sir Antonio has devoted his energies to the service of the public, and having taken a leading part in the preservation of Epping Forest for the people, was appointed a judge in the "Verderer's Court for the Forest of Epping." He also took great interest in the work of church extension, and was a member of the Ray, the Palæontographical and Geological Societies; he was also in the Commission of the Peace for Westminster. The deceased married, in 1837, Maria, eldest daughter of the late Mr. George Kelner, of Ipswich, by whom he leaves a son, the Rev. Nicholas Brady, M.A., and two daughters.

But it is in his character of a geologist that we must now speak of Sir Antonio Brady. So long ago as 1844 his attention was attracted to the wonderful deposits of brickearth which occupy the Valley of the Roding at Ilford, within a mile of his residence. Encouraged by Prof. Owen and other eminent palæontologists, he commenced to collect the rich series of mammalian remains which the Thames Valley brickearths yield. Owing, however, to their porous nature, the bones had lost, during their long interment, all their gelatine, and the earlier "finds," when exhumed, were so soft and friable that they crumbled beneath the touch, and it was not until fresh gelatine had been introduced that it was found possible to preserve these magnificent remains of the old inhabitants of this district. In his Catalogue of the Pleistocene Mammalia from Ilford, Essex (1874, 4to, printed for private circulation only) Sir Antonio Brady pays a just tribute of respect to the genius and ability of his first instructor in the art of preserving fossil bones, and acknowledges that he was indebted to Mr. William Davies, F.G.S., of the British Museum, for the preservation of most of the larger specimens in his collection.

Some idea may be formed of the enormous riches of this deposit when we find that an amateur, in his leisure hours, was able to amass nearly one thousand specimens of Mammalia from a single locality, comprising: *Felis spelæa*, *Canis vulpes*, *Ursus*, sp., *Elephas primigenius*, *E. antiquus*, *Rhinoceros leptorhinus*, *R. megarhinus*, *R. tichorhinus*, *Equus fossilis*, *Megaceros Hibernicus*, *Cervus elaphus*; *C.* sp.; *Bison priscus*; *Bos giganteus*, *Hippopotamus*, sp. To this interesting series of fossil remains of the old fauna of the Thames Valley, we may add that the subsequent researches of Prof. Boyd Dawkins, F.R.S., and R. W. Cheadle, Esq., F.G.S., have added the "Musk ox," *Ovibos Moschatus*, and the labours of F. C. J. Spurrell, Esq., F.G.S., the "Lemming." We have thus presented to us in this area the conjunction of the Northern and Southern forms of land-animals as marvellous as that which modern London exhibits to-day, in its assemblage of specimens of the genus Homo, from

every clime. For with the *Hippopotamus*, the *Rhinoceros*, and the Lion from the south, we have also in abundance the *Cyræna fluminalis*, a shell now characteristic of the Valley of the Nile and the rivers of India and China: whilst from the north advance to meet them the "Musk-Ox," the Reindeer, and the Lemming; we have also evidence at Walthamstow of the Elk (*Alces malchis*).

To Sir Antonio Brady, then, we are indebted for a most valuable collection of Pleistocene mammalia, now happily preserved in the British Museum of Natural History, Cromwell Road. Nor must we omit to mention that he strove by his presence, as a resident at Stratford, and by his constant acts of kindness and hospitality to the workmen, and by the *largesse* which he freely gave, to rescue from destruction these intere ting relics of a pre-historic age, which now help to swell the magnificent series of our National Museum.

HENRY WOODWARD

BRIGHTON HEALTH CONGRESS

THE Brighton Health Congress, which was opened on Tuesday, December 13, and which has been accompanied by an Exhibition of Domestic, Sanitary, and Scientific Appliances, has been one of the most successful of its kind, and by far the most successful of any of a purely local character. In origin and in progress it has, throughout, been Brightonian, and although many of the scholars who communicated addresses and papers were outsiders, they came by invitation. To the Congress in the course of the week no less number than 1200 added their names as Associates, while the Exhibition was at all times well filled, some 400 persons per day, independently of the Associates, paying for admission. It is estimated, indeed, that altogether between four and five thousand persons have been present. We stated last week that the Exhibition was presided over by Lord Chichester, and the Congress by Dr. Richardson; and we gave a detail of the sections and order of proceedings: we shall dwell more particularly on the addresses and papers which were submitted.

The President's Opening Address

Dr. Richardson took for his theme "The Seed-Time of Health." In the opening passages he drew a picture of life and death in the time when the ancient Greeks were in the meridian of their intellectual existence. In the midst of the night, when the sun cannot see the deeds of men, certain of these were depicted carrying a dead child, in all its beauty, to the pyre. They carried it in this solemn silence and darkness because of the shame they felt that anything so young and beautiful should die in what ought to be the seed-time of health. Upon this he drew a sharp and striking contrast from our own time. He pointed out the great mortality of our children, for which we have grief, fond memories, but no shame. We accept the events, in short, as if they were natural, and erect memorials of them.] After illustrating these points, the causes of the great mortality of the young were classified under four heads—the inherited, the accidental, the inflicted, and the acquired. Under the first head the influence of hereditary diseases were discussed; under the second head the diseases of an epidemic character, and which occur from exposure to one or other of the communicable poisons, were considered; under the third head the injuries arising from bad nursing, excessive competition in education, and improper feeding, were brought under notice; and under the fourth head the evils incident to early resort to smoking, the use of stimulants, late hours, and irregular meals, were made subjects of comment. What now is wanted, said the President, was the ideal of a new nobility. In the wild-boar days of human existence; in days when men, hardly emancipated from lower forms of life, crept out of their caves, their huts, their walled prisons, to see their nobler species go forth to exercise those rude arts of hunting, fighting, revelling, which formed the whole art of civilisation, there was a nobility which deserved the name—the representative of necessity. But now, when these arts have degenerated into mere childish imitations, mere apedoms of the great past, they are but injurious pretensions for nobility of soul and body. Once noble, according to the spirit of their day they are in this day ignoble. The address concluded with two applications of thought, one general, the other local. The general requested those who rule and govern us to look at the seed-time of health as it is, and take it as the test of good or bad government. The local was addressed to the people of Brighton, that the meeting then commencing might be truly useful, and the date from whence they should move onwards until the shame of mortal events, which the sun should never witness, be felt whenever they occur.

Section A.—Health of Towns

The president, Mr. Edwin Chadwick, C.B., opened the Section on Wednesday with an address on the prevention of epidemics. He set out by describing the various means adopted to stay the great outbreak of cholera in 1848, in which he took a prominent part, and the deductions made from observations then taken. The conclusions that had been come to then were that to aggregate disease in large hospitals was only to increase the danger, and that the very best means of preventing the spread of infection was by the adoption of sanitary measures at the places where, in the cycle of epidemics, they were to be expected. He described in a very interesting manner the precautions taken at York, at Merthyr Tydvil, at Mevagissy in Cornwall, and other places, and the gradual decrease of deaths that followed, and he showed that similar precautions taken at St. Petersburg, Malta, and Memphis, had had the same result. At St. Petersburg, for example, the deaths had decreased from 25,000 to 3000 in the successive decade. Some other equally startling statistics were given by Mr. Chadwick. By the returns of the Local Government Board, he calculated that we had saved in the death-rate from disease or infection a quarter of a million of lives, and three million cases of sickness, and putting this at a money value, 5*l.* for death and 1*l.* for a sickness, over four millions of money had been saved. In conclusion he portrayed with poetical picturesqueness a possible future "when medical science shall occupy itself rather with the prevention of maladies than their cure, when governments shall be induced to consider the preservation of a nation's health as important as the promotion of its commerce or the maintenance of its conquests, and when we may hope to see approach a time in which, after a life spent almost without sickness, we shall close the term of an unharassed existence by a peaceful Euthanasia."

The papers which followed the delivery of Mr. Chadwick's address were all of them good, and some of them of unusual excellence. Mr. Easton's account of the water supply of Brighton was exceedingly interesting and able. It led to a sharp and animated debate on the water softening process in large towns. Mr. Easton and the Mayor, while advocating the principle of softening water, seemed inclined rather to look upon it as a household than a municipal duty. They were opposed by several other speakers. Mr. Griffiths followed with a paper on the escape of foul gases from ventilating gratings on the main sewers of towns. The gist of his argument was that the faults were rather in the houses than in the sewers. If, he maintained, the sewer system of houses was so perfect that nothing could be retained in the sewer pipes, and if the houses were thoroughly cut off from the sewer, the risks of escape of gas were greatly reduced. What was wanted in the sewer was a current of air, not ventilation at one point. The defective house drainage

throughout the country was the evil that required the most speedy rectification.

Dr. Mackay supplied an excellent paper on the geology and climate of Brighton in relation to health. He gave many details, and finally came to the conclusion that the general view was correct, that autumn was the best season for Brighton. The freshness and coolness of the town in the early summer ought also to be remembered.

Dr. Fussell pleaded the necessity for recreation spaces in all large towns. He said there were about 100 towns in England containing upwards of 25,000 inhabitants, and that much of the decrepitude and high mortality amongst the young was caused by the excessive density of the populations.

Mr. Ellice Clark dwelt on the anomalies in the administration of the sanitary laws; and Dr. Browning read paper on the correlation of public health and sanitary legislation.

One of the most interesting essays read in this section was by Mr. Frederick Walsh, and was entitled "Sanitation in Japan, a Comparative Study." Mr. Walsh, who has resided long in Japan, detailed the diseases most prevalent there, together with an account of the mode of application of the sewage for agricultural purposes. He condemned very strongly the system of London drainage, and argued against the loss which was sustained in consequence of that system, contending that we had created by it most of the evils of which we complain.

The last paper read in this section was by Mr. H. F. Lester, on "Reform in Slaughterhouses." The author described tersely the present condition of private slaughterhouses, and contended that the great reform required in them consisted in the erection of public *abattoirs* in all our large towns. The paper led to a brisk discussion, the general sentiment being in favour of the views expressed by the author. Owing to an accident of arrangement a paper by Mr. W. S. Mitchell, M.A., entitled "A Comparison of English and Foreign Watering Places," had to be taken as read.

Section B—Food in Relation to National and Domestic Economy

The president, Mr. J. R. Hollond, M.A. M.P., opened the Section on Thursday with an address on the subject of the "Production, Distribution, and Economic Use of Food." In considering the first head, he maintained that until the conditions under which the land was held were modified, and a much larger portion of the land brought up to the level of the best farming, it was premature to speak of the limit to the production of bread and meat having been nearly reached. He noticed the obstacles to agriculture in our land customs and the imposition of extraordinary tithe on market and hop gardens. Our landed system hampered the nominal owner in his power of dealing with his land; our system of transfer stood in the way of a ready change of ownership, and the cultivator had insufficient security for the capital he put into his business. Under the second head he said Free Trade for us was not only a benefit, but a necessity, and commented upon the way in which the English food-producer was hampered by the heavy carrying-rates of the railway companies, and advocated the market system of Paris. In treating of the economic uses of food he advocated the use of vegetables in greater variety, and in regard to alcoholic drinks, from the point of view of making the most of the means at command, thought the outlay on them might with advantage be made elsewhere. In conclusion he alluded to the unsatisfactory results of our cooking arrangements and the wastefulness entailed thereby. He expressed himself in favour of teaching cookery in schools in a systematic way.

Dr. C. B. Drysdale then read a paper on "Cheap Food and Longevity," and showed by the statistics of New Zealand that, while the other circumstances were not specially favourable, as against this country, there was a lower death-rate, calculated at 12 in 1000 annually, combined with great cheapness of food. He contended also that the comparative scarcity of food here was caused by the higher birth-rate, which should be publicly discouraged in all European states.

Mr. A. F. Halcombe read a paper of special excellence on "New Zealand as a Source of Food Supply," showing the great capacity of New Zealand for furnishing us with food, and the prospects ultimately of large supplies being obtained from this growing colony. The writer supported also the statements made by Dr. Drysdale as to the healthiness of the New Zealand Climate.

Miss Yates followed with a paper on Bread Reform. She especially recommended the use of wheatmeal bread. She urged the members to support this movement for the sake of the children who are ill-nourished from being fed on impoverished white bread.

Mr. T. B. Lightfoot, in a very lucid paper on the "Preservation of Food by Cold," detailed the various steps of the dry-air freezing process, and stated that there need be no further difficulty in supplying the demands of this country with wholesome fresh animal food if the matter be approached in a scientific and business-like spirit. His paper elicited from the President of the Congress the fact that he (the President) had seen the carcases unpacked from Australia, had examined the preserved flesh, had partaken of it, and had come to the conclusion that the scientific difficulties were solved, and that nothing but commercial cupidity at home stood in the way of abundant supply of cheap food for the working classes.

A paper by Mr. Wynter Blyth, on "Rational Feeding and Eclectic Dietetics"; another paper by Dr. Whittle, on "Artificial Dieting of Infants"; another by Mr. Cowan, "On Honey as an Article of Food"; and still another by Mr. Mitchell, on "Lessons on Foods," led up to a final address by Major Hallett, on "Food-Plant Improvement." In this paper Major Hallett described his remarkable experiments and successes in improving the growth of wheat and other cereals, together with his latest experiments upon the growth of the cotton-plant, all of which we must reserve for another and special occasion.

Evening Lecture—Propagation of Disease through Food and Drink, by R. P. B. Taafe, M.D., Medical Officer of Health for Brighton

Dr. Taafe's lecture was a very carefully prepared reading on the diseases of the body which are propagated through food and drink. He dealt first with the introduction of parasitic diseases in this way, next of the zymotic. He presented in a very clear manner the views of those who support what is called, commonly, the germ theory of disease. Finally he dwelt upon the subject of prevention, and at the conclusion of his lecture received a very hearty vote of thanks.

Section C—Domestic Health, including Educational Training

Dr. Alfred Carpenter on Friday delivered the presidential address on "Domestic Health." He dwelt upon the public indifference in regard to matters of health, and expressed his belief that there was a border-line between health and disease, in which the conditions necessary for the establishment of disease must have time to produce their results before the disease actually arose. Speaking of zymotic diseases, he urged that their very existence was an evidence that natural waste was retained somewhere in too close a proximity to particular persons who became subject to disease. He dealt with the error of sending wastes into sewers, and proceeded to show that these wastes as soon as they became such, changed their character unless properly and naturally dealt with by being given to the earth. The address was very warmly received.

The papers that followed were so numerous that

although the section sat until nearly six o'clock they could not all be read.

The first by the late Sir Antonio Brady on "Prevention of Smoke in Fire Places" was read by Gen. Alexander, one of the secretaries of this section.

Mr. H. H. Collins followed on "Home Sanitation and House Inspection," the practical common sense of which was that every man and woman should be their own sanitary inspector.

Mr. Burton, for Prof. Fleeming Jenkin, argued the importance of associations with an annual subscription, for sanitary inspection.

Dr. Strong, of Croydon, supplied various hints on domestic sanitation, supporting earnestly a constant instead of an intermittent water supply. Mr. Bailey Denton treated on the subject of the domestic filtration of water, giving a description of the common filters in use, with special reference to those in the exhibition. Mrs. King created a great interest by an essay on "Health in Relation to Clothing," in which she proposed a radical change for the better in the clothing of women. Mr. Alderman Hallett, Mayor of Brighton, described an every-day process for the domestic softening of water from the chalk, and illustrated his paper by one or two simple and very neat experiments.

Mr. Henry C. Stephens took up the subject of public elementary education in relation to public health, presenting an exceedingly thoughtful and practical communication, in which it was urged that in the beginning of life the senses should be more carefully trained by easy exercise of observation, analysis of impression, and muscular training in connection with mental effort.

The proceedings of the section were brought to a close by an address singularly felicitous in style and matter, by Major Robert Edis, F.S.A., on "Sanitation in Decoration."

General Meeting

At the conclusion of the sectional sitting which, like all the others, had been held in the Dome, the President took the chair for the general meeting, at which the usual formal votes of thanks were moved, seconded, and carried, together with the following resolution of condolence and sympathy: "That this meeting has heard with the deepest regret of the death of their much esteemed and distinguished colleague, the late Sir Antonio Brady, and hereby requests the President of the Congress to convey to Lady Brady and her family the sincere condolence of the members in an event which to them and the public is so great a bereavement." After the general meeting a large number of the Associates attended the "Health Congress Dinner" in the Banqueting Room of the Royal Pavilion.

Lecture to the Working Classes, by Brudenell Carter, F.R.C.S.

The proceedings of the Congress were brought to a fitting close on Saturday evening, Dec. 17, by the lecture delivered to the working classes, as well as to the Associates, by Mr. Brudenell Carter. The lecturer took for his topic "Eyesight," and for an hour and ten minutes held the large audience in closest attention. He first treated on the evolution of the eye as an optical instrument; next he described the structures of which the instrument is composed; thirdly, he discussed the irregularities of structure, dealing specially with the two irregularities, short sight and colour-blindness; lastly, he treated on the practical application of the knowledge of visual defects in its relation to educational training. The bad practice of teaching children to read and write with their eyes close to the paper, by which the defect of short-sightedness is so extensively produced, was strongly condemned, as well as the faults connected with bad light, bad paper, and irregular and imperfect printing.

The Exhibition

We should be remiss if we did not add a few lines on the Exhibition. The managers of this department struck out quite a new line in making it something more than sanitary. They called it a domestic, sanitary, and scientific exhibition, and this enabled them to introduce various things that add to the useful and the ornamental, as well as the healthful. All kinds of electrical apparatus that could serve in the house were shown. Various kinds of mechanical contrivances, and numerous objects for illustrating artistic improvements, such as painting of walls in corridors, halls, staircases, and rooms. Horological instruments found a place, and a great number of instruments for recording time were under constant inspection. In addition, the bicyclists and tricyclists had their department, and were presented with a goodly show of these new machines for pleasurable and useful exercise. In a word, all was so excellently classified, selected, and arranged that on the whole we never remember to have seen so good an exhibition. In the six visits we made to it we cannot express correctly which pleased us most, the place itself and its exhibits, or the extraordinary interest with which all the visitors, rich and poor alike, took in it. Everybody seemed to show an intelligent desire to collect all practical information that could be obtained; and when from this task they passed to the fine art Loan Collection which the authorities at South Kensington had the kindness and excellent taste to supply, the transition from the useful to the beautiful was indeed a pleasurable sight.

The peculiar feature of the Brighton Health Congress was its character as an example. In numbers and importance of papers read and discussed it rivalled some of the organised congresses, which having the metropolis as their centre, proceed to different towns and make them for a short season their platform. There can be no doubt that there is some danger to what are called the peripatetic societies in this initiation. If the town of Brighton can call together twelve hundred members to a congress, secure papers for various important sections, command the services of efficient officers, issue a volume of Transactions, and get together a scientific exhibition that shall attract several thousands of visitors, what may not larger towns accomplish, such as Birmingham, Manchester, Leeds, Newcastle, Liverpool, Edinburgh, and Glasgow. These immense places cannot possibly be expected to remain uninfluenced by the example set by Brighton and the results of the example. If then each town takes to forming its own congresses, there will soon be little ground left for congresses on the visit. Towns will vie with towns in organising instead of receiving meetings organised for them to receive. For our part, however, we augur nothing but good from such a new departure and new development. The light of science and knowledge will only burn all the brighter in a place out of which it has been struck; and as every town must invite to its congresses the same workers as would go if they followed the peripatetics, the characters of the different meetings will be the same in effect and usefulness.

ANCIENT TIDAL ACTION AND PLANES OF MARINE DENUDATION

THERE is at least one question in ancient physical geology on which the speculations of Prof. R. S. Ball (NATURE, vol. xxv. pp. 79, 103) regarding the magnitude of Tidal Waves in times past seem to throw fresh light, namely, the origin of "planes of marine denudation." For those readers of NATURE who may not be familiar with this term, first proposed by Prof. Sir A. Ramsay, let me endeavour briefly to describe them. If we protract to a true scale the outlines of certain tracts of the British Isles, of Europe, or of America, we shall find

that the higher portions of the ridges tend to rise to a certain level, which, on being connected by an imaginary plane, form a gently-sloping surface over a considerable area, it may be of hundreds or thousands of square miles in extent. Now, if in addition to this we insert the stratification of the district crossed by the section, and taken from actual observation, it will often be found that this imaginary plane is formed of the truncated edges of highly-inclined strata, or of the denuded summits of anticlinal arches of contorted or folded strata. When such strata are of hard and tough materials it is clear that they must have been planed down by an agent of great power and of long-continued action, but the result has been to convert originally highly uneven surfaces of flexured strata into approximately horizontal surfaces, over which inequalities have been worn off. Through such planes the existing river-valleys have been cut down, but between neighbouring valleys there is to be found the intervening ridge, trending upwards to the original, now imaginary plane. The Silurian district of Central Wales offers a remarkable example, which has been used by Prof. Ramsay ("Mem. Geol. Survey," vol. i.). Let any one on reaching the summit of one of the long ridges to the south of Cader Idris place his head on the ground, and in this position survey the tract of hilly country lying to the southwards, and he will realise the nature of the plane surface, out of which the valleys have been hollowed. But there are many more remarkable instances even than this. The central plain of Ireland is an example on a larger scale, over which the Middle and Upper Carboniferous rocks have been swept away, leaving a floor of limestone; but it would be impossible to explain the course of its great river, the Shannon, without referring its origin to a time when a sloping plain stretched from the present sources of that river amongst the Leitrim Hills to Shannon harbour below Limerick, because now its channel traverses a ridge of Old Silurian rocks at Killaloe, which could not have existed *as such* when the river first commenced to run over a tract formed of Carboniferous beds since denuded. But it is amongst mountainous districts that the evidence of the former existence of old planes is most remarkable, because least expected. The higher ridges of the Grampians seen at a distance, or accurately drawn from a hypothetical standpoint (as on Mr. Knipes' panoramic picture), forcibly bring home this idea to the mind. The ridges and peaks with very few exceptions tend to rise to an imaginary plane connecting the higher elevations, while several actual terraces coincide with the plane itself. Out of this old plane the existing valleys have been cut down, during the vast period of time descending from the pre-Devonian to the present. A still more ancient plane was that in which the Cambrian sandstones and conglomerates were strewn, formed of tough gneiss and hornblendic schists, with a gentle rise towards the east. The Scandinavian Promontory offers an illustration on a grand scale, and to these we might add the pre-Triassic plane formed of the denuded Devonian and Carboniferous rocks of Belgium and the Rhine highly tilted, convoluted, and contorted, through which the existing rivers have carved out their channels. But I refrain from adding additional illustrations, as I must pass to the consideration of the question, How have such ancient planes been formed? Where was the agent capable of abrading down hundreds or thousands of feet of the most obdurate rocks over hundreds or thousands of square miles, and of transporting power sufficient to carry away the *débris* of these vast ruins? The geologist answers, "Only give me an unlimited time, and the waves, tides, and currents of the seas acting along the coast-lines as they at present act, will effect all that you demand." Granted that with "unlimited" time all this may be effected, but this is a demand which the astronomers will not concede, and geologists must pay some respect to astronomers and mathematicians after all. But even with the aid of (practically) "unlimited" time a serious objection meets us at the threshold. It is undeniable that the crust of the earth is always on the move, either upwards or downwards; those who are not intensely uniformitarian in their views contend that this oscillatory motion of the crust was much more rapid in past geological times than at the present day. If this be admitted, and I hold that it is a necessary consequence of the constantly decreasing rapidity with which the secular cooling of the surface has progressed downwards to the present day, how, let me ask, are you to get the coast to remain sufficiently long within range of such wave action as we see at present, to admit of the abrasion of the land to any considerable distance. The effects of wave action along our existing coasts, where formed of the more solid strata, is admittedly very slow, and in order to produce any great planing effects, the same coast-level (approximately) must be presented to it for a lengthened period; but with the required (practically) "unlimited" time, the coast-level would be placed out of reach, either by elevation or submergence. The hypothesis of approximately unlimited time seems to me, therefore, to be untenable. And what *we require is not time but force*, in order to account for the planing away of vast masses of obdurate strata over extensive areas. Such additional force Prof. Ball has supplied us with. He has shown that at a comparatively early stage of geological history the tides may have had a denuding effect several hundred times more powerful than the present. With such a "stupendous tidal grinding-engine" we may indeed conceive the work we have to account for accomplished, and the hypothesis of Prof. Ball approaches certainty, when it is considered that the character of the floors of the sea adjoining our coastlines gives but slight evidence that such planes of marine denudation as I have attempted to describe, are in course of formation at the present day. They are phenomena of the past, not of the present, when wave and tidal action has, happily for mankind, subsided into restricted limits as compared with that of Palæozoic and Mesozoic times.

EDWARD HULL

TELEGRAPHS IN CHINA

ON December 2 a telegram was received from Reuter's agent at Shanghai, announcing that the telegraph line between that town and Tientsin was finished. In a few weeks we may expect to hear of the completion of the line to Peking. The capital of the Chinese empire, the chief seat of bigotry and hostility to foreign innovation, will then be in direct communication with Europe and America. There is, we believe, no doubt in the minds of those acquainted with the origin of this undertaking, that political motives alone dictated it. Hitherto, during the winter, when the mouth of the Peiho was closed by ice, couriers taking from twenty to thirty days on the journey travelled down the Grand Canal to the Yangtsze conveying letters to Shanghai; or they were sent across Manchuria, in from fifteen to twenty days to Kiachta, where they reached the Great Northern Telegraph Company's Siberian lines. These slow and uncertain modes of communication with the outer world were severely felt by the Chinese Government during the winters of 1879 and 1880, when its relations were almost broken off with Russia, when the land and sea forces of the latter were hanging like a thundercloud on the frontiers of China, and a peaceable solution of the Kuldja question seemed impossible. It was then brought home to the Peking authorities that their coasts might be invaded, their principal cities captured, and the foe be almost at their gates weeks before they heard the news. The bitter experience of these years taught the Chinese a hard lesson, but one which they speedily took to heart. Long before the Marquis Tsêng brought the question to a

peaceable conclusion the Chinese Government had ordered large quantities of telegraph material from England, and within a few months of the ratification of the treaty with Russia, we find the port of Peking connected by telegraph with the rest of the world. The Chinese may occasionally be slow in their mental processes, but the present instance shows that when once the utility of an innovation is clearly presented to their minds, they seize and assimilate it with a rapidity worthy of their more mercurial neighbours, the Japanese; and this, it will be observed, is as true of the Government as of individuals.

It is not yet known how far the new lines will be open for public use; but, judging by the rapid spread of other foreign inventions in China when once introduced, we cannot be far wrong in anticipating a vast extension of the telegraph for all purposes in that country. Ten or twelve years ago there was hardly a Chinese-owned steamer engaged on the coasts or inland waters of the empire; 84 per cent. of this trade is now carried on in Chinese bottoms. Large and well-appointed steamers, Chinese-owned and manned, now ply to every port along the coast and on the Yang-tsze. As we write, a Chinese steamer has arrived in the Thames, bringing several native merchants who are about to enter into competition with us on our own ground. From time to time we have recorded in NATURE the various stages in the progress of the new telegraph line, because it marks one of the most important steps that has ever been made in China towards the adoption of the results of Western science and civilisation. It is one of the very few improvements which she has adopted without external advice and pressure; in this instance she has sat at the feet of the best of all teachers, experience, and has profited by its precepts. Nor is the event any the less important when we reflect on the development possible for the other appliances of steam and electricity, now that the ice of dislike and distrust of innovation has been spontaneously broken. The intelligence and enterprise of the three hundred millions of the people of China will not long remain content with a single line of telegraph across a comparatively small corner of their vast territory. A race of men with strong mercantile instincts who seize with avidity on every time—or labour-saving appliance, the Chinese, now that their government has abandoned its most cherished prejudice, may well be expected to call for the extension of an invention such as the telegraph.

We may fitly conclude this attempt to forecast the future in China of one of the most remarkable productions of western science in the nineteenth century, by mentioning the lesson which may well be derived from our past intercourse with that country. It is worse than useless to thrust our improvements by force or threats on the Chinese. When left themselves to the results of their own experience and slow methods of thought, their advances, though occasionally tardy, are surer and more satisfactory. It can hardly be a matter for wonder that a people who have been taught to revere the teaching of their sages for nearly 3000 years as the highest products of human wisdom, and whose minds have been cast in the same mould from a period long anterior to our era, should look askance at the inventions of the modern man of science who knows nothing of the system of ethics and politics of Confucius and Mencius, and the other sages of antiquity. A few years ago a foreign company in China constructed, without the formal sanction of the Chinese authorities, a line of railway a few miles in length between Shanghai and Woosung, at the mouth of the Shanghai River. The government repeatedly called for the cessation of the traffic on the ground that its consent had not been obtained, and that it did not want railways in its territories. Finally, in order to prevent any complications respecting ownership, it purchased the line, destroyed it utterly, and sent the materials to Taiwan in Formosa, where, according to the latest accounts, they were lying rotting; and they did all this notwithstanding the arguments and protests of foreign ministers and diplomatists. They were determined at all cost to rid themselves of an innovation which had been thrust on them. On the other hand, a recent *Peking Gazette* published a memorial from the Governor-General of Shansi, one of the most powerful officials in the Empire, requesting authority to lay down a line of railway to certain mines in his province. Preliminary surveys have already been made, and the memorialist goes so far as to demonstrate to the Emperor that had such a railway been in working order a few years ago, much of the misery and horrible loss of life in the Shantung famine might have been prevented. It is from bitter experiences such as these that the Chinese learn; the devices of diplomatists or promoters are thrown away on them.

THE VOYAGE OF THE "VEGA"[1]

THE voyage of the *Vega* will be in many respects one of the most memorable events in the history of navigation. For the first time a continent has been circumnavigated, so far as authentic record goes, and at last the North-East Passage has been won, after heroic efforts begun nearly three and a half centuries ago. As Baron Nordenskjöld reminds us in these volumes, the North-West Passage, although explored, has never been navigated entirely by any ship, McClure's famous journey having been accomplished partly in sledges over the ice. But the voyage will be still more memorable by the two rich volumes in which it finds copious record, volumes which have scarcely a parallel in the whole literature of geographical exploration. For Baron Nordenskjöld has not contented himself with merely telling the story of his own successful voyage and its results. That voyage, as we have said, crowns the efforts of centuries, and it has been by the results of these efforts that the *Vega* has accomplished her work with scarcely an adverse incident. It will be remembered that some six years ago Baron Nordenskjöld showed that the voyage from Norway to the mouth of the Yennissei could easily be accomplished in a week or two, if taken at the proper time. Since then trading ventures have gone over the course every year, and a regular trade-route may be held as established by the well-informed enterprise of the eminent Swedish professor. For something like twenty years Baron Nordenskjöld has been at work in the seas to the north of Europe, and mainly in Spitzbergen, and the rich results of them are known to all students of science, and their story was told about two years ago in an interesting work noticed in these pages. Thus he became probably more familiar with the ice-conditions of these northern seas than any other authority; and his success in the Yennissei expedition led him to think that there was no reason why the whole North-East Passage should not be navigated. But Baron Nordenskjöld is, above all, a man of science, and accustomed to go about his work in a scientific method. That he has the true spirit of adventure is proved by the work of half his lifetime, but then he has a weakness for entering upon his enterprises with his eyes open, of knowing where he is going, and what are likely to be the results to science. So before making up his mind about the North-East Passage, the Baron examined carefully all the records of previous voyages along the north coast of Europe and Asia, from the time of Othere, a thousand years ago, down to the latest adventures of the brave Norwegian skippers. Thus he found that at one time or other the whole of this stretch of coast had been navigated piecemeal, except the most northerly point of the old continent, Cape Chelyuskin,

[1] "The Voyage of the *Vega* round Asia and Europe; with a Historical Review of previous Journeys along the North Coast of the Old World." By A. E. Nordenskjöld. Translated by Alexander Leslie. Five steel portraits, numerous maps and illustrations. Two vols. (London: Macmillan and Co., 1881.)

which had baffled all the attempts of those daring Rus-

FIG. 1.—A, the Common Skua; B, Buffon's Skua; C, the Pomarine Skua.

sian sailors of the seventeenth and eighteenth centuries, who, in "floating coffins" and with many disasters, had explored the entire coast of Siberia. Baron Nordenskjöld saw that the ice in these regions has its times and seasons. To set out earlier than the middle of July he found would be to court delay and disaster. About that time the ice about Novaya Zemlya and in the Kara Sea begins to break up, and later on it generally retires from the north coast of Asia, being liable, however, to be blown south again by a north wind. In ordinary seasons, however, he inferred from the records of previous voyagers, a broad free lane of water might be looked for on to Behring Straits. In this respect the north coast of Asia differs materially from that of America. The eastern half of the latter is so hemmed in by islands that the ice has no scope for retiring completely, and so the North-West Passage under existing conditions is almost impossible for a ship. The fact that the ice is so easily blown black by a north wind to the coast of Asia gives ground to infer that a ring of islands stretches from Franz Josef Land to Wrangel Land, an inference confirmed by other characteristics. With his scheme so clearly and fully worked out, Baron Nordenskjöld went to the King of Sweden, who gave it hearty support. The result was that the king, in conjunction with the munificent Mr. Oscar Dickson of Gothenburg, who has spent a fortune in the cause of science, and Mr. Sibiriakoff, a Siberian merchant, agreed to advance the funds for an expedition round the continents of Europe and Asia. The *Vega*, a barque-rigged steamer of the best oak, 357 tons register, with engines of 60 horse-power, steaming 6 to 7 knots an hour, was bought, and specially fitted for her peculiar work. A staff of officers and men of science was carefully selected, and a picked crew of twenty-one men, with Baron Nordenskjöld himself as the leader of the expedition. The chief officer was Capt. Palander, of the Royal Italian Navy; Dr. F. R. Kjellman acted as botanist, Dr.

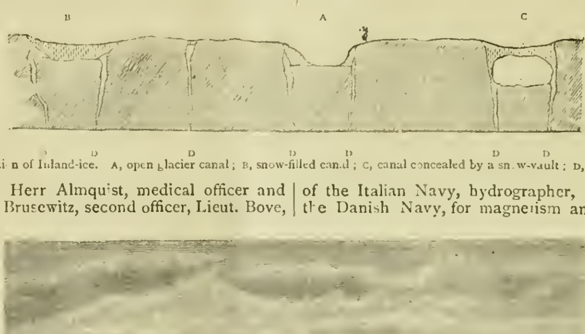

FIG. 2.—Section of Inland-ice. A, open glacier canal; B, snow-filled canal; C, canal concealed by a snow-vault; D, glacier-clefts.

Stuxberg, zoologist, Herr Almquist, medical officer and lichenologist, Lieut. Brusewitz, second officer, Lieut. Bove, of the Italian Navy, hydrographer, Lieut. Hovgaard, of the Danish Navy, for magnetism and meteorology, and

FIG. 3.—Glacier with stationary front, Udde Bay, on Novaya Zemlya, after a drawing by Hj. Théel (1875).

Lieut. Nordquist, of the Russian Guards, interpreter and zoologist. Baron Nordenskjöld, besides being eminent as a geologist and mineralogist, we need not say, was a host in himself. It will thus be seen that the expedition was perfectly equipped for scientific work.

We have said that Baron Nordenskjöld's work is far

more than a mere narrative of the voyage of which he was the organiser and commander. Not only does he give an exhaustive account of all previous voyages in these regions, but enters into the amplest details as to the scientific results achieved up to the present time. The work is thus a mine of unusual richness for the student of science, while it is so written as to be not only intelligible but delightful to any ordinary intelligent reader. As the *Vega* pursues her course, the leader stops every now and then to tell his readers of the voyages associated with a particular region, or of the knowledge we have of its geography, geology, and biology. Many matters of the widest scientific importance thus come to be introduced, and questions discussed of burning interest in various departments of science. In following the course of the *Vega* we shall attempt to give our readers some faint idea of the riches stored up in these two volumes.

The *Vega* was accompanied by the *Lena* as far as the mouth of the river of that name, for the commercial navigation of which she was destined, and part of the

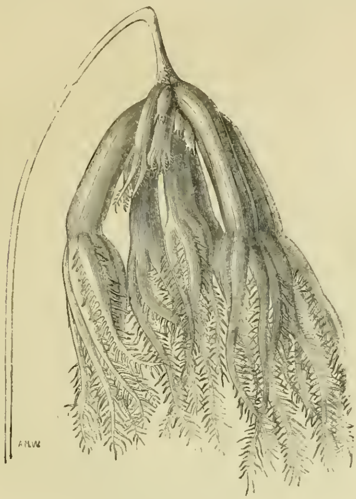

FIG. 4.—Umbellula from the Kara Sea.

way by the *Fraser* and *Express* as tenders. Coming round from Karlskrona, the expedition left Tromsoe on July 21, 1878. At Moosoe, near the North Cape, it was discovered that cloudberries and rum formed an excellent antidote to scurvy, and a stock was laid in, and whether from their use or from the carefully regulated diet on board the *Vega*, of which details are given, there was not a trace of scurvy during the whole voyage, and indeed no illness at all to speak of. As he rounded the corner of Europe, the Baron stops to tell us of early voyages in this direction, of Othere, whose story was told by King Alfred, Willoughby and Chancellor, Pet, and Jackman, and others, and to show us some old maps in which the coast is rudely laid down. The work is specially rich in maps from the tenth century down, including a large scale map of the north coast of Europe and Asia, in which the *Vega's* data have been incorporated. The vessels *rendezvoused* at Yuger Schar, between Waygats Island and the mainland on July 31. And here opportunity is taken of telling us all that is known about the Samoyeds of the island and mainland, from the earliest voyages down to the visit of the *Vega*, with abundant illustrations. Then follows a chapter of the greatest possible interest on the animal world of Novaya Zemlya, which becomes really an account of Arctic zoology. First we have a complete account of the birds, with wealth of illustration. The variety is wonderful, and evidently the habits of the interesting creatures have been carefully studied by Baron

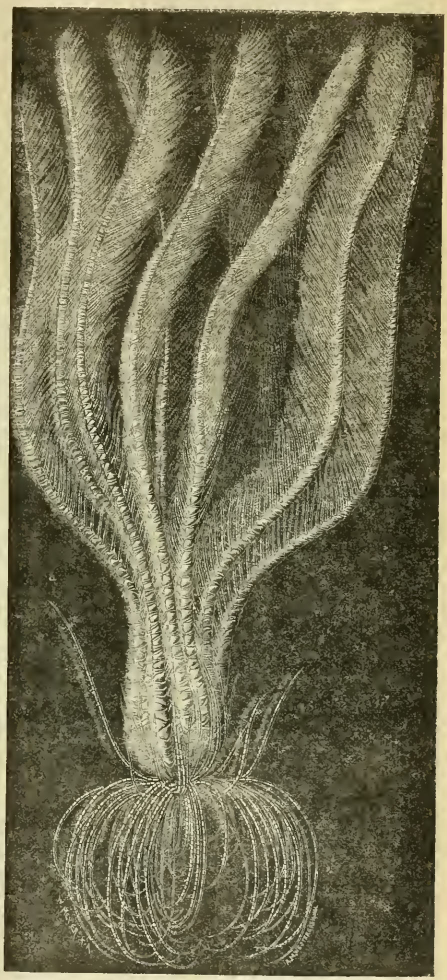

FIG. 5—Hairstar from the Taimur Coast (three-fifths of natural size).

Nordenskjöld. Here, for example, is a graphic picture, with its accompanying illustration (Fig. 1):—

"Often during summer in the Arctic regions one hears a penetrating shriek in the air. When one inquires into the reason of this it is found to proceed from a kittiwake, more rarely from a glaucous gull, eagerly pursued by a bird as large as a crow, dark-brown, with white breast

and long tail-feathers. It is *labben*, the common skua (*Lestris parasitica*, L.), known by the Norwegian walrus-hunters under the name of *tjufjo*, derived from the bird's cry, '*I-o i-o*,' and its shameless thief nature. When the 'tjufjo' sees a kittiwake or a glaucous gull fly off with a shrimp, a fish, or a piece of blubber, it instantly attacks it. It flies with great swiftness backwards and forwards around its victim, striking it with its bill, until the attacked bird either drops what it has caught, which is then immediately snapped up by the skua, or else settles down upon the surface of the water, where it is protected against attack. The skua besides eats eggs of other birds, especially of eiders and geese. If the eggs are left but for a few moments unprotected in the nest it is immediately to the front and shows itself so voracious that it is not afraid to attack nests from which the hatching birds have been frightened away by men engaged in gathering eggs only a few yards off. With incredible dexterity it pecks a hole in the eggs and sucks their contents. If speed is necessary this takes place so quickly and out of so many eggs in succession that it sometimes has to stand without moving, unable to fly further until it has thrown up what it has swallowed. The skua in this way commonly takes part in the plundering of every eider island. The walrus-hunters are very much embittered against the bird on account of this intrusion on their industry, and kill it whenever they can. The whalers called it 'struntjaeger'—refuse-hunter—because they believed that it hunted gulls in order to make them void their excrements, which 'struntjaegeren' was said to devour as a luxury. The skua breeds upon low, unsheltered, often water-drenched headlands and islands, where it lays one or two eggs on the bare ground, often without trace of a nest. The eggs are so like the ground that it is only with difficulty that they can be found. The male remains in the neighbourhood of the nest during the hatching season. If a man, or an animal which the bird considers dangerous, approaches the eggs, the pair endeavour to draw attention from them by removing from the nest, creeping on the ground and flapping their wings in the most pitiful way. The bird thus acts with great skill a veritable comedy, but takes good care that it is not caught."

Again he tells us of the snow-bunting:

"During excursions in the interior of the land along the coast, one often hears, near heaps of stones or shattered cliffs, a merry twitter. It comes from an old acquaintance from the home land, the *snoesparfven* or *snoelaerkan*, the snow-bunting (*Emberiza nivalis*, L.). The name is well chosen, for in winter this pretty bird lives as far south as the snow goes on the Scandinavian peninsula, and in summer betakes itself to the snow limit in Lapland, the *tundra* of North Siberia, or the coasts of Spitzbergen and Novaya Zemlya. It there builds its carefully-constructed nest of grass, feathers, and down, deep in a stone heap, preferably surrounded by a grassy plain. The air resounds with the twitter of the little gay warbler, which makes the deeper impression because it is the only true bird's song one hears in the highest north."[1]

Then Baron Nordenskjöld goes on to do for the mammalia the same service he has done for the birds, beginning with the reindeer. It thrives as far north as 80° and 81°, and in a temperature of − 40° to − 50° C.

"It is remarkable that the reindeer, notwithstanding the devastating pursuit to which it is exposed on Spitzbergen,[2] is found there in much larger numbers than on North Novaya Zemlya or the Taimur Peninsula, where it is almost protected from the attacks of the hunter. Even on the low-lying part of South Novaya Zemlya the reindeer, notwithstanding the abundance of the summer pasture, is so rare that when one lands there, any reindeer-hunting is scarcely to be counted on. It first occurs in any considerable numbers farther to the north, on both sides of Matotschkin Schar."

Notwithstanding the immense destruction of the reindeer in recent times their numbers in Spitzbergen keep so well up that it has been supposed they migrate from Novaya Zemlya. But Baron Nordenskjöld shows that this is not the case, as the reindeer of the two islands belong to different races. The fact that *marked* reindeer have been found in Spitzbergen has also led to the supposition that they found their way from some more northerly inhabited land, a supposition that does not seem probable, but is certainly worth verifying. Then we have our old friend the Polar bear, followed by the mountain-fox and the lemming. The marine life of these northern regions makes up amply for any scarcity of life on land.

"Here animal life is exceedingly abundant as far as man has succeeded in making his way to the farthest north. At nearly every sweep the dredge brings up from the sea-bottom masses of decapods, crustacea, mussels, asterids, echini,[1] &c., in varying forms, and the surface of the sea on a sunny day swarms with pteropods, beroids, surface-crustacea, &c."

Of the higher animal types of these seas the walrus, now that the right whale is nearly extinct, is the most important, and therefore comes in for a long notice. Even the walrus has suffered greatly from excessive hunting, and unless precautions are taken, will go the way of the right whale. The walrus haunts particular places of Novaya Zemlya and Spitzbergen, attracted by the abundance of their special food, which does not consist, as is often stated, of seaweed, but of various living mussels from the bottom of the sea, principally *Mya truncata* and *Saxicava rugosa*. Seals and whales are also referred to at some length.

Through Yugor Schar the vessels steamed their way into the Kara Sea on August 1. And here we are told a great deal about inland ice and icebergs, and the rich life-conditions of the Kara Sea, its surroundings and hydrography. The remarks on inland ice are specially valuable, the subject being illustrated by the writer's extensive experience in Greenland and Spitzbergen. We reproduce here (Fig. 2) a section which he gives of inland ice, and a picture of a Novaya Zemlya glacier (Fig. 3). The inland ice, Baron Nordenskjöld tells us, is of too inconsiderable extent to allow of any large icebergs being formed. There are none such accordingly in the Kara Sea, and it is seldom that even a large glacier ice-block is to be met drifting about. Indeed the Baron tells us that the popular notion as to the frequency of true icebergs in the far north is quite erroneous, the actual fact being that icebergs occur in far greater numbers in the seas which are purely accessible. The abundance of life in the Kara Sea is remarkable, though this has only been recently known, the old notion on this point being quite erroneous. As a specimen of the life to be found in this sea, we give here an Umbellula (Fig. 4).

Dickson's Harbour, at the mouth of the Yennissei, was reached on August 6, and so the first stage of the voyage was happily completed. Beyond this all was new, but it seemed to be felt that if Cape Chelyuskin was safely passed, all the rest would be comparatively easy. Here upwards of 100 pages are devoted to various topics of

[1] There are, however, various other song-birds found already on south Novaya Zemlya, for instance, *lappsparfven*, the Lapland bunting *Emberiza lapponica*, L.), and *berglaerkan*, the shore-lark (*Alauda alpestris*, L.). They hatch on the ground under bushes, tufts of grass, or stones, in very carefully constructed nests lined with cotton-grass and feathers, and are not uncommon.

[2] The hunters from Tromsoe brought home, in 1863, 996; in 1869, 975; and in 1870, 837 reindeer. When to this we add the great number of reindeer which are shot in spring and are not included in these calculations, and when we consider that the number of walrus-hunting vessels which are fitted out from Tromsoe is less than that of those which go out from Hammerfest, and that the shooting of reindeer on Spitzbergen is also carried on by hunters from other towns, and by tourists, we must suppose that at least 3000 reindeer have been killed during each of those years. Formerly reindeer stalking was yet more productive, but since 1870 the number killed has considerably diminished.

[1] Echini occur only very sparingly in the Kara Sea and the Siberian Polar Sea, but Novaya Zemlya at certain places in such numbers that they almost appear to cover the sea-bottom.

interest suggested by the arrival of the Expedition at the mouth of the Yennissei. Evidence is given to prove that the lower Yennissei must at one time have been thickly inhabited, but is now quite deserted, probably owing to the difficulty of procuring food, a difficulty that may be solved by the enterprises begun by Baron Nordenskjöld. A long list of phanerogams is given, collected during the stay of the expedition. Some interesting dredging results were obtained, and on this subject Baron Nordenskjöld writes :—

"For the science of our time, which so often places the origin of a northern form in the south, and *vice versâ*, as the foundation of very wide theoretical conclusions, a knowledge of the types which can live by turns in nearly fresh water of a temperature of + 10°. and in water cooled to − 2°·7, and of nearly the same salinity as that of the Mediterranean, must have a certain interest. The most remarkable were, according to Dr. Stuxberg, the following: a species of Mysis, *Diastylis Rathkei*, Kr., *Idothea entomon*, Lin., *Idothea Sabinei*, Kr., two species of Lysianassida, *Pontoporeia setosa*, Stbrg., *Halimedon brevicalcar*, Goës, an Annelid, a Molgula, *Yoldia intermedia*, M. Sars, *Yoldia* (?) *arctica*, Gray, and a Solecurtus."

On the long Yalmal Peninsula on the west of the Gulf of Obi, the author collects all the information known, but that is not much. The ground everywhere seems to consist of sand and sandy clay, and Baron Nordenskjöld, when he landed, could not find a stone so large as a bullet or a pea. Two chapters are devoted to a history of the navigation of the North-east Passage from 1556 to 1878; an admirable summary, containing much that is the result of the author's own research, and which never before has seen the light. Especially is this the case

Fig. 6.—The *Vega* and *Lena* saluting Cape Chelyuskin.

with the numerous Russian voyages of the seventeenth, eighteenth, and nineteenth centuries, of which little is known, but the results of which Baron Nordenskjöld acknowledges have been of the greatest service to him in forming his own plan. To the efforts of the Norwegian walrus hunters, too, Carlsen, Tobiesen, Johanessen, and others, he does full justice; and indeed their contributions to science have often been of substantial value; Johanessen, was awarded two medals by the Swedish Academy for his discoveries.

Port Dickson was left on August 10, and as the *Vega* steamed north-east to Chelyuskin over an imperfectly mapped coast, she came across many new islands, and other novelties which we cannot refer to in detail. Animal life along the Taimur coast was much scarcer than in previous parts of the voyage, though on the other hand the sea yielded some fine specimens. We give as an example a hairstar (Fig. 5) from off the coast.

The northern promontory of Asia was reached on August 19, and Baron Nordenskjöld describes the landscape as "the most monotonous and desolate I have ever seen in the High North" (Fig. 6). Here, however, we must leave the *Vega* till next week.

(*To be continued.*)

NOTES

Taking a retrospective *coup d'œil*, in a recent issue of his paper, of the Paris Exhibition, Count du Moncel notes, among other points, the marked success of the lectures, and the eagerness of the public to be instructed. A permanent electrical exhibition, with like facilities, would greatly promote the development of electric industries. The number of practical electricians in France is at present very limited, and while there are some very skilful makers of telegraphic apparatus and instruments for

electrical physics, yet (if electroplating be excepted) there are no great industries giving rise to electric works like those of the cable-manufacturing houses in England, or those of Siemens and Felten in Germany. The Count hopes "our *élan* henceforth will not be confined to mere publication of electric papers." Again, a desideratum at the Exhibition was the attachment of placards to apparatus, indicating its object and general arrangement. This is a matter worth attention in our forthcoming Exhibition. At first there was some talk about giving evening concerts at the Paris Exhibition, but the fact that the city had agreed with the concert at Besselièvre, behind the Palais de l'Industrie, not to allow any concert performances within a radius of 100 m., was a difficulty. It is doubtful (the Count says) if such concerts would have much increased the evening attendance, which was always large. With regard to the Crystal Palace Exhibition, he considers it should have been put off for a year.

ON the proposition of M. Cochéry, Minister of Posts and Telegraphs, the Minister of Foreign Affairs and President of the Council has nominated Dr. Warren De La Rue, F.R.S., correspondent of the Institute (Academy of Sciences), a Commander of the Legion of Honour, in recognition of his services at the Electrical Congress and as vice-president of the jury. We regret to learn that Dr. Warren De La Rue, in consequence of ill health, has been compelled to resign the important post of Honorary Secretary to the Royal Institution.

THE Lightning-Rod Conference formed by delegates from the Meteorological Society, the Royal Institute of British Architects, the Society of Telegraph Engineers, and the Physical Society, which has been at work since November, 1878, has at last completed its labours and prepared its report, which, together with an enormous mass of information that has been most assiduously got together, will very soon be published. The report will consist of a brief description of the purposes which a lightning-conductor is intended to serve; a statement of those features in the construction and erection of lightning conductors respecting which there is a great difference of opinion; and the final decision on the points in question arrived at by the Conference. It will also contain a simple code of rules for the erection of lightning-conductors which any ordinary non-technical individual will be able to understand. It is hoped that the success of the publication will justify the labour that has been expended upon it. It will be published in the form of a book by Messrs. Spon and Co.

IN view of the recent great development of the telephonic system, the Directors of the Magdeburg Fire Insurance Company have lately sought information from the Secretary of the Imperial Post Office, Dr. Stephan, as to whether the danger from lightning was increased by the overhead wires and iron supporting rods, and whether special conditions of insurance should be made for houses in proximity to such wires. Dr. Stephan has replied that no case had yet come to his notice in which lightning had done injury in the way referred to. The experience of the German Post Office with telephone lines was indeed short; but in other countries there was an experience of overhead telegraph lines, which was of several years' extent, and he was not aware that observations had occurred in this connection which had given any occasion for anxiety about lightning. It was important, in arranging those telephone lines, to take care that any atmospheric discharges which might affect them should have a sufficient path to earth. Such being the case the telephone wires might even afford houses a protection against lightning which they would otherwise lack. The directors of the insurance company think it at present unnecessary, therefore, to make any change in their terms in the case of houses over which telephone lines pass.

WE regret to have to record the death of Mr. Charles Moore, the well-known geologist of Bath. Mr. Moore was known as a most indefatigable and successful collector. On one occasion he carted from a fissure near Bristol two tons of the celebrated bone-bed. This when sifted and examined afforded no less than 45,000 teeth, besides portions of many fish and reptiles. Most important of all, it yielded nineteen teeth of the Triassic mammifer *Microlestes*, which Mr. Moore had thus the good fortune to discover. On another occasion he astonished the British Association by his power of predicting from the forms of nodules the genera of fish which would be found inclosed in them when they were broken open. His interesting discovery of Liassic shells in lead veins traversing the carboniferous limestone was the subject of a most valuable communication to the Geological Society, and he was also one of the first to recognise the importance of the Rhætic formation in this country. The Museum at Bath owes much to the persevering labours of Mr. Charles Moore.

A REUTER's telegram, dated New York, December 18, announces the death of Dr. Isaac J. Hayes, the Arctic explorer. Dr. Hayes, it will be remembered, was surgeon of Dr. Kane's second Arctic expedition, with which he returned to the United States in 1855. A conviction that there existed an open Polar sea induced him in 1860 to undertake a voyage of exploration on his own account. He sailed from Boston in the schooner *United States*, and by means of sledges he penetrated as far north as 81 deg. 37 min. He again visited Greenland in 1869. To the last he was desirous of heading another expedition to the North Pole by way of Smith's Sound. His voyage in the *United States* was described in "The Open Polar Sea;" and among other works from his pen were, "An Arctic Boat Journey," relating to his first voyages; "Cast away in the Cold," a supplementary narrative of his second voyage, published in 1870; and an account of Greenland under the title of "The Land of Desolation." The Geographical Society of London and the Société de Géographie of Paris awarded him gold medals for his discoveries.

THE death is announced, at the age of seventy two, of the Rev. Dr. John Ludwig Krapf. Dr. Krapf was a missionary of the Church Missionary Society in East Africa from 1837 to 1853, and did much for the exploration of the region north-west of Zanzibar, in company with Dr. Rebmann. They are known specially as the discoverers of Kilimanjaro and Mount Kenia.

IN a paper published in the July number of the *Archives des Sciences Physiques et Naturelles* of Geneva, which we referred to at the time, M. F. Forel established, by observations of the oscillations of the lowest extremity of the glacier of the Rhone since 1856, that, although two causes determine the position of the end of a glacier, nevertheless the chief of them is not the fusion of this end by the summer heat, but the rate of advance of the glacier. As the latter depended upon the thickness of the glacier, he concluded that the variations of the length of a glacier depend chiefly upon the variations of its thickness. Measurements having shown considerable variations of thickness at the lower end of the Rhone glacier, these might be easily explained by very small changes in the thickness of the *nevé*, which changes are, so to say, exaggerated by the mutual relation of the rate of advance and the thickness, producing thus immense changes in the length of the glacier. Glacialists will appreciate the great importance of these observations of M. Forel, as they may explain an immense increase of glaciers without great variations of temperature, but only by small changes in the distribution of snow and rain which fall upon a country. However, as is pointed out by those glacialists who have sought for the key of the glacial period in an accurate

study of what is going on now in Arctic countries, this relation has been rather neglected. In a second paper, which has just appeared in the November number of the *Archives*, M. Forel discusses the influence of ablation on the thickness of a glacier, the ablation, together with the amount of snow fallen on the surface of the *nevé*, being the two chief causes of changes in thickness. Our knowledge of the influence of ablation is almost nothing; but the influence due to an increase, or decrease, of the feeding of a glacier being felt, and exaggerated, throughout the whole length of a glacier, while the ablation has an importance only in its lower parts, M. Forel concludes that this second cause never would have the importance of the first. In any case both causes never can be simultaneous, the *nevé* taking fifty or a hundred years to reach the low end of the glacier; thus the thickness of a glacier at this end depends upon the quantity of snow fallen on the *nevé* some fifty or a hundred years ago, and on the ablation during a few recent years, which causes may be either concurrent, or opposing, in increasing or decreasing the thickness. He remarks also that altogether it seems that the retreat of glaciers, which reached its maximum about the year 1875, was not a local phenomenon, but was simultaneously observed in the Austrian Alps, in the Pyrenees, in the Caucasus, in Scandinavia, and in Greenland. M. Forel concludes by asking the naturalists of all countries to indicate the advance and retreat of glaciers as much as possible in figures, and to measure the thickness of glaciers at several well-determined parts.

WE fear all hope must be given up as to the safety of Mr. Powell in the *Saladin* balloon. A balloon was seen on the night of the 16th, going by Santander and Bilbao towards the sea, but nothing more has been heard of it. It may have been the *Saladin*, but if so, and Mr. Powell had been in it and conscious, he would certainly have made some sign. Mr. Powell was an ardent and intelligent aëronaut, and his death, which we fear is only too certain, must be regarded as a loss to science in the pursuit of scientific knowledge.

THE Royal Italian Scientific Institution at Venice offers a number of prizes for various memoirs. Among them we note the following two as of more general interest:—(1) "A Statement of the Hypotheses recently advanced by Physicists on the Causes of the Phenomena of Light, Heat, Electricity, and Magnetism" (prize 3000 lire (about 110*l.*), term March 31, 1883). (2) "A Systematical and Critical Enumeration of the Cryptogamic Plants hitherto observed in the Venetian Provinces" (prize and term for this treatise are not yet fixed).

THE death is announced, on November 29 last, of Dr. Wilhelm Weith, Professor of Chemistry at Zürich University. He died in the Island of Corsica, where he was staying on a visit, at the early age of thirty-seven years.

IN the night of November 19–20 the tunnel through the Col di Tenda, on the frontier between France and Piemont, was broken through. Cuneo is the nearest place on the Italian side of the mountain, where the Italian railways will join the new French branch extending through the tunnel.

WE have on our table the following books:—Cultivation of Liberian Coffee, by H. A. A. Nicholls (Silver and Co.); Report of the Scientific Results of H.M.S. *Challenger*, 1873–76, Vol. iii. Zoology; Koumiss, by G. L. Carrick (Blackwood); Every-day Life in Our Public Schools, edited by C. E. Pascoe (Griffith and Farran); Statistical Atlas, Parts x. and xi., by C. P. Bevan (W. and A. K. Johnston); Perfect Way in Diet, by Anna Kingford (Kegan Paul); Educational Theories, by Oscar Browning (Kegan Paul); The Bedfordian System of Astronomy, by J. Bedford (H. Vickers); Description of the Chemical Laboratory at the Owens College, Manchester, by Prof. H. E. Roscoe, F.R.S. (Cornish); Ideality in the Physical Sciences, by B. Peirce (Little, Brown and Co.); European Ferns, by James Britten (Cassell, Petter, and Galpin); The Encyclopædic Dictionary, by Robert Hunter (Cassell, Petter and Galpin); John Amos Comenius, by S. S. Laurie (Kegan Paul); Elementary Treatise on Electricity, by Prof. Clerk Maxwell (Clarendon Press); Astral Origin of the Emblems and Hebrew Alphabet, Rev. J. H. Broome (Stanford); Encyclopædia Brittannica, vol. xiii. (A. and C. Black); Old Greek Education, by J. P. Mahaffy (Kegan Paul); Practical Chemistry, by Howard (William Collins); British Almanack and Companion (Stationers Company).

THE following recently-published Norwegian and Danish books may interest some of our readers:—"A Geological Description of the Lofoten and Vesteraalen Districts of Norway," by K. Pettersen, with maps, and with interesting remarks on the coal-bearing Jura formation of those provinces; "A Flora of Iceland," by M. Chr. Grönlund, being the results of his visits to Iceland during the years 1868 and 1876, from which he has brought back very rich collections of plants; the flora of Iceland includes, according to M. Grönlund, 870 species, of which 332 are Phanerogams, the total number having to be increased by many Algæ; "From Fields and Forests: Pictures of the Life of Insects," in two volumes, by M. v. Bergsöe; and a pamphlet, by M. R. Lehmann, on the former coast-lines in Norway.

S. A. LEXE, who steadily pursues his studies on the recent geology of Norway, contributes to the last number of the Norwegian *Archiv* for mathematics and natural science, a paper on the upheaval of Norway, and its coast-lines and terraces.

ADVICES received at Plymouth give some particulars of a destructive typhoon which visited Haiphong and Tallee on October 8, causing great destruction and loss of life. The wind blew with tremendous violence, and the heavy sea flooded the whole of the surrounding country. In Tallee there were six feet of water in the houses three and four miles distant from the sea-shore. The current was so strong that it swept away the entire town, the number of persons drowned being estimated at over 3000.

IN the December number of the serial *Auf der Höhe*, Prof. Palmieri, the Director of the Observatory on Mount Vesuvius, communicates a discovery with regard to volcanoes. In a series of spectro-analytical examinations of the lava Prof. Palmieri has, it is stated, just discovered a new line which corresponds exactly with that of helium, the famous element hitherto seen in the solar spectrum only.

THE displacement of *isotherms* (or lines drawn through places having an equal mean temperature), with the season, has some interesting practical bearings. Several years' recent (so-called) phenological observation in Sweden proves that in general each phenomenon of plant-life occurs only at a certain temperature. A similar rule applies to the arrival of many birds of passage. Comparing the times such phenomena take to advance one degree of latitude, it is found on the Baltic coast that their greatest velocity is in midsummer. The numbers of days for an advance of one degree are in sundry cases as follows:—Freeing of lakes from ice 6·0, flowering of April plants in Southern Sweden 4·3, of May plants 2·3, of June plants 1·5, of July plants 0·5, appearance of leaves (general average) 2·3, ripening of fruit 1·5, fall of leaves 2·3, freezing of lakes 5·1. A recent study by Herr Hildebrand (of Upsala) of the movement of isotherms in the north of Europe throws light on these facts, showing (among other things) that while in Sweden the rate of the movement increases with the temperature, in Russia it remains nearly constant. The author gives a number of maps for various temperatures. Taking 0° it is found that the isotherms running nearly north and south move eastwards, but in

the interior of the continent they are bent at a right angle, extending east and west, and moving to the north. In the map for 9° the influence of greater heating of land than of sea is apparent. The isotherms are nearly straight lines east and west, and move from south to north. For 12° they extend west-south-west to east-north-east, and move towards north-north-east.

IN the wave of administrative economy which has passed over Japan during the past three years, education has, we regret to notice, suffered. The allowance to the Education Department for the current year is only 914,601 *yen* against 1,181,100 *yen* last year—a reduction of 266,499 *yen*, or nearly 25 per cent. The expenditure on working the mines has also been diminished nearly 50 per cent. It is right to observe, however, that the estimates of every department have been largely cut down, and that much of the decrease under the head of education may be attributed to the substitution of native teachers for highly-paid foreign professors.

MR. H. TRUEMAN WOOD, Secretary of the Society of Arts, asks us to draw the attention of our readers to the Exhibition of Photographic Apparatus which the Society proposes to open next month. They hope to be able to include in the Exhibition apparatus illustrating some at least of the many applications of photography to scientific purposes, and Mr. Wood will be very grateful to any person who will entrust the Society with any such apparatus to be shown during the short time the Exhibition will remain open. Mr. Wood will gladly send full particulars of the Exhibition to anybody sufficiently interested in the matter to apply for them.

PROF. R. S. BALL, Royal Astronomer of Ireland, will give the first of a Course of Six Lectures on the Sun, the Moon, and the Planets (adapted to a juvenile auditory), at the Royal Institution on Tuesday next, the 27th instant.

A VIOLENT shock of earthquake is reported from Agram on November 20, at 8.27 a.m. The duration of the shock was two seconds, its direction perpendicular, and its intensity so great that a panic was caused, and the schools remained closed for the day. Earthquakes are reported (1) from Stassfurt, where a violent shock occurred on December 2 at 4.18 a.m., causing considerable damage in the salt-mine of Leopoldshall; (2) from Siders (Valais), where a strong shock was noticed on December 4 at 2.55 a.m.; (3) from Agram, where a shock of two seconds duration occurred on December 9 at 9.55 a.m.

THE annual meeting of the Geographical Society of Paris has been held for the first time under the presidency of M. de Lesseps. The meeting was numerous and enthusiastic. M. de Lesseps gave an address in which he eulogised his predecessor, Admiral La Roncière le Noury, who died recently. On the following evening the usual banquet took place at the Hotel Continental.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, presented by Capt. Wyld; two Squirrel Monkeys (*Chrysothrix sciurea*) from Demerara, presented by Mr. F. N. Apthorp; a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Capt. C. Hollard Smith; two Ferrets (*Mustela furo*) from Japan, presented by Mrs. J. F. Faed; a Bosch-bok (*Tragelaphus sylvaticus*) from South Africa, presented by Mr. E. W. Berryman; a Rose-coloured Pastor (*Pastor roseus*) from India, presented by Mr. F. Lubbock; a Herring Gull (*Larus argentatus*), a Greater Blacked-backed Gull (*Larus marinus*), European, presented by Mr. E. W. Ebsworth; six Dwarf Chameleons (*Chamæleon pumulus*) from South Africa, presented by Col. Hassard, R.E.; a Green Monkey (*Cercopithecus callitrichus*), a Mona Monkey (*Cercopithecus mona*) from West Africa, a Cerastes Viper (*Vipera cerastes*) from Algeria, deposited; four Snow Buntings *Plectrophanes nivalis*), two Common Siskins (*Chrysomitris spinus*), British, purchased.

OUR ASTRONOMICAL COLUMN

A VARIABLE OF THE ALGOL TYPE.—A telegram to the Earl of Crawford's Observatory at Dunecht, notifies that Mr. Sawyer of Boston, U.S., has detected a variable of the comparatively rare type of Algol, with a period of 5·24 days, its brightness varying between 6·0 and 6·7, and 1881, November 30·84 being an epoch of minimum. It is number 854 of Sir J. Herschel's third series of observations with the 20-feet reflector, published in Vol. iii. of the *Memoirs* of the Royal Astronomical Society; it is there called 5m. with a minute companion 88° n.p. 25", and a note says, "not in Piazzi": these observations were made in 1827-28. The star is Lalande 31384, observed 1797, May 24, and estimated 6½; Bessel calls it 7m. in July 1822, and Santini has the same magnitude at the end of July or beginning of August 1838. Lamont has two observations at which it was estimated 7m. and 8m. In the *Durchmusterung* it is 5·5, and on the Atlases of Argelander and Heis 6m. Schjellerup called it 7·7 on 1863, June 9, and in his catalogue of 1864 he pointed out the differences in the estimated magnitudes of previous observers. Dr. Gould, in the *Uranometria Argentina* mentions that a series of comparisons between August and October 1871, indicated "an oscillation of magnitude from 6·0 to 6·5, but exhibiting no regular law in the variation"; in the catalogue he has "6·7 var.?" Taking into consideration the estimates of various observers it might be inferred the true limits of magnitude may be somewhat wider than assigned above. The position of the star for 1882·0 is in R.A. 17h. 10m. 33s. Decl. + 1° 20'·6.

A PROBABLE VARIABLE-STAR.—The following is a case which appears to be worthy of attention:—D'Agelet observed a star in 1783, on July 26, 27, and 29, which he estimated on the three nights 6, 6, and 6·5 respectively. It is No. 5057-59 in Dr. Gould's reduced Catalogue, and there called *Anonyma*: in fact it is not found, so far as we know, in any modern catalogue except the *Durchmusterung*, where it is +17°, 3997, and estimated only 9·4. The place of the star from D'Agelet, brought up to 1880·0, is in R.A. 19h. 27m. 22·10s., Decl. +17° 29' 28"·0·

THE BINARY STAR η CASSIOPEIÆ.—The elements of this beautiful revolving double-star, which had been already calculated by Duner, Doberck, and Gruber, in 1875 and 1876, have been newly investigated by Ludwig Struve, son of the present director of the Imperial Observatory at Pulkowa. The principal characteristic of the new orbit consists in its depending entirely upon the measures of Bessel and the two Struves between 1830 and 1878, the early data of Sir W. Herschel, which, if taken into account, would exercise an influence much greater than is due to their degree of accuracy, being left out of consideration. The resulting elements are as follow:—

Periastron passage ...	1905·02	Inclination ...	56° 22'
Node	45° 3'	Eccentricity ...	0·6296
Node to periastron ...	238°·17	Semi-axis major	8"·786
For Eq.	1850·0	Period of revolution	148·90 yrs.

Duner had found the period 176, Gruber 195, and Doberck 222 years. A comparison with the measures of Dembowski (1856-76) and Duner (1868-75) exhibit constant differences, upon which M. O. Struve remarks at some length in a note to his son's memoir (*Bulletin de l'Acad. des Sciences de St. Petersbourg*, tome v.).

According to the above orbit the components close in until the year 1907, when their apparent distance is at a minimum of 1"·9 on an angle of about 305°. To test the longer and shorter periods we have:

	In Doberck's Orbit.		In L. Struves's Orbit.	
1882·0 ...	162°·1 ...	5"·54	165°·8 ...	5"·44
1883·0 ...	164·6 ...	5·51	168·1 ...	5·40

M. Otto Struve's observations gave for the parallax of this star 0"·1543 ± 0"·0450, whence the mass of the two components results 8·33 times that of the sun, and the author of the memoir further concludes that the larger star has a mass 6·57 times, and the smaller one 1·76 times the solar mass. Prof. Auwers finds the proper motion of η Cassiopeiæ + 0·1346s. in right ascension, and − 0"·481 in declination, or 1"·196 in great circle, in the direction 113°·7.

SOLAR PHYSICS [1]

II.

WE now have to consider what is the best method by which we can obtain, not a reversed image of the infra-red region, but a direct image of that portion of the spectrum ; the problem had to be attacked in an experimental manner. It was really a matter of physics, and nothing more ; the chemical question was *hors de combat.* Every silver salt which I have already shown you, you saw absorbed in the blue end of the spectrum, and not in the red ; and therefore from what I had previously told you, you were prepared to hear that those salts would not be photographically effective for the red end of the spectrum, although they would be eminently so for the blue end. The question then we asked ourselves was this : Is it possible to obtain a silver salt which shall absorb in the red end of the spectrum? Is it possible, for instance, to obtain a salt of silver which will exhibit two molecular states—one absorbing in the blue, and the other in the red? If we turn to other bodies I think I can show you that there are bodies which exist in two or more molecular states. The very example of obtaining a reversed negative in the red of the spectrum by Draper's plan is an example of it. I have here another very good example of the oxidation process. This is chloride of silver paper which has been darkened by white light, and you will see that it has a tint which naturally would absorb to a certain extent the red rays. You will further see by the oxidising action we are able to produce a coloured oxide of silver. In other words, we have a coloured spectrum produced by the action of light itself, owing to the oxidising process. Alongside of this is the spectrum, taken on similar paper, without any preliminary exposure to light. You see where we get a darkened salt we have an impression of the spectrum in various colours, beginning with the blue, green, and then the red of the spectrum. Where the red end of the spectrum is you have a red oxide of silver formed.

Now let me show you that there are two different molecular states of elementary matter with which we are well acquainted. First of all I will throw a spectrum on the screen, and try to show you that there are two forms of iodine which absorb in different parts of the spectrum, telling us that they are molecularly different, when in solution at all events. The spectrum is on the screen, and I place a solution of iodine which has been dissolved in water in front of the slit, and you see that it cuts off the whole of the blue end of the spectrum, leaving only a red band. If you look at the white screen on the wall on the right you willsee an image of the slit reflected from the back of the prism, which gives the real colour of the iodine in solution. In this form, then, we have one molecular state of iodine. We will take another molecular state obtained by dissolving it in bisulphide of carbon. You see that we have a totally different absorption. The yellow is cut out, and the blue and also the red are left behind. Here, then, is one proof that we can have two molecular states of an element. But there is another interesting example in gold. If you will allow me to read from a book written by my colleague, Mr. Lockyer, he refers to the two molecular states of gold ; and if possible, I should like to show you those different molecular states as far as we can on the screen. After talking about different kinds of spectra he goes on to say : "Gold is sometimes yellow, as you know, but gold is sometimes blue and sometimes red. It must be perfectly clear to all that if particles vibrate, the colours of substances must have something to do with the vibrations. If the colours have anything to do with the particles it must be with their vibrations. Now as the spectrum in the main consists of red, yellow, and blue, the red and the blue rays are owing to something in a substance which only transmits or reflects the yellow light : if we put gold leaf in front of the limelight, we can see whether the yellow light does or does not suffer any change. The yellow disappears ; we have a green colour ; the red and blue are absent. The gold leaf is of excessive thickness. What would happen could I make it thicker? Its colour would become more violet. This I have proved by using aqua regia. But we can obtain a solution of fine gold which lets the red light through. Its particles are doing something with the blue vibrations. We can obtain another solution which only transmits the blue. Now what is the difference—the 'particular' difference—between the gold in these solutions and that which is yellow by reflected light, and green or violet by transmitted light? It is a question worthy of much study." [1]

I will now throw on the screen an image of a thin film of gold kindly lent me by Mr. Lockyer, and you will see the colour of gold as it really is. It is not yellow, as we ordinarily know it, but is green when of that particular thickness, and it cuts off the red of the spectrum. I have here a solution of gold, which however does let red light through. It is purely metallic gold precipitated in water, and you will see what a beautiful red colour this has. This ruby colour of gold was first obtained by Dr. Hugo Müller, and experimented upon by Faraday. You can obtain also another solution of gold which is a greenish blue. It is rather a ticklish thing to show on the screen, but I daresay we shall be able to show it to you. Thus, then, we have gold in three states : the red molecular state, the blue molecular state, and the green molecular state ; or perhaps the green may be referred to the difference between those two, or a combination of those two. Evidently, then, it is possible to obtain matter in two or three molecular states at the very least.

Now to apply this to our silver salts. Experience seems to show that the green molecules will be much more likely to absorb in the red than the blue molecules. I will just try to explain this by passing one or two green bodies before the slit of the spectrum apparatus (Fig. 6). In this green glass, for instance,

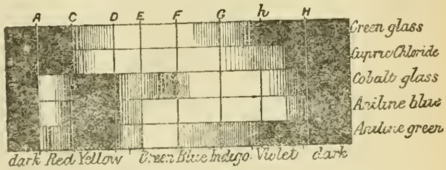

FIG. 6.—Absorption spectra of different coloured matters.

you see that the red is cut off markedly from the green. Now if we take a solution of a salt of copper—chloride of copper—you will remark that the same phenomenon presents itself ; we have the red cut off as well as the blue. You may ask the question whether a blue colour may not be equally as effective in absorbing the red as the green. I think I can answer this question experimentally. Here we have a piece of ordinary blue glass ; you will see that although the red of the spectrum is dimmed to a certain extent, still a streak of red appears, and the principal absorption takes place in the yellow. One would naturally infer that as the red was not entirely cut off, those rays which lie below the red would also not be cut off. That, practically speaking, is found to be the case. We will take an ordinary blue dye, and you will find that we get the same phenomenon occurring. You will notice that the image of the slit on the side screen is a most beautiful Oxford blue, and you notice in the spectrum that it is gradually cutting out the yellow. Such experiments might be multiplied, but from what you have seen it is evident that a green is more likely to be effective as a red absorber than is blue, and this would apply also to the silver salt as regards the molecular state which we wish to produce.

You may ask me—why cannot we use a green dye according to Vogel's method, which I mentioned last time? I can show you on the screen what would have happened with a green dye. There are greens and greens : some greens absorb in the red, others do not. In the ordinary green dye, which is a very complex body, part of the blue and part of the yellow is cut off, but not the red or the green, and consequently, as the red appeared it was perfectly useless to attempt to dye a film in order to produce a photograph of that end of the spectrum. What remained then to do? It simply remained to take some *simple* silver salt itself, and then to convert it into the molecular state, which would absorb the red. After four years of labour we succeeded in effecting this. In this test-tube we have some precipitated bromide of silver, which, as you saw on the screen last time, is of a yellow tint, or rather of an orange tint. Now bromide of silver is to a very small extent soluble in nitrate of silver, more particularly when acidified with nitric acid ; and if such bromide of silver as we have here be boiled in a solution of

[1] Lecture delivered on May 25, 1881, at the Lecture Theatre, South Kensington Museum, by Capt. Abney, R.E., F.R.S. Continued from p. 166.

[1] P. 129, "Studies in Spectrum Analysis." by J. Norman Lockyer, F.R.S. ; "International Scientific Series." (Kegan Paul and Co.)

nitrate of silver together with nitric acid, particular particles of bromide of silver are dissolved by the nitrate of silver, and then are re-deposited, built up, as it were, into bigger and bigger molecules, until finally we find we have a bromide of silver which literally is green when placed before the lantern. These two plates are respectively coated with the two kinds of bromide; first we have the ordinary bromide; and second, the bromide modified in molecular structure in the way I have described. The light from the lantern traverses the two films placed side by side, and you will see that they are eminently different in every way: the one being of an orange tint, absorbs the blue rays, the other being of a greenish-blue tint, absorbs the red. Now to show you that those two states are identical as far as the chemical composition of the molecules is concerned, I will take the green bromide of silver film which I had just now, and rub it with my finger; you will find that the blue bromide is once more reconverted into the red bromide. It has been scratched a little

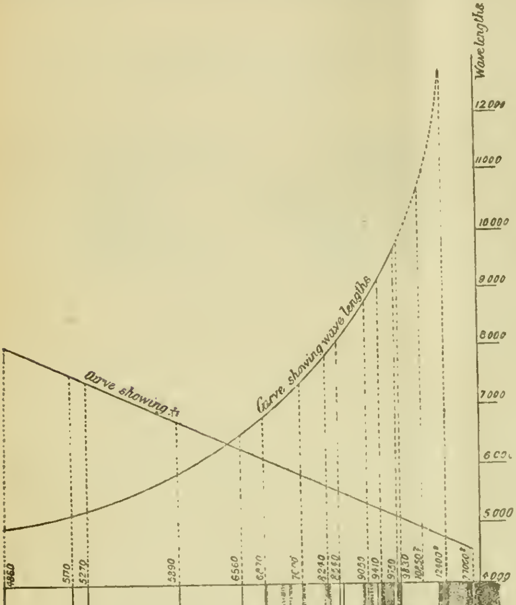

Fig. 7.—Diagram of the least refrangible portion of the solar spectrum.

in the rubbing, and you will see, where the scratching has taken place, that it is of a fine orange tint. Here then we have a solution of the problem, the production of a bromide which will absorb in the red as well as one which can absorb in the blue, which is the ordinary state.

Now no sooner was this bromide obtained than, of course, there was great interest displayed to test its effect as regards its being a photographic salt. To do this we naturally appealed to the spectrum. But here I have something which will be perhaps more efficacious in showing you what that salt can do than anything else. This is a photograph of the poles of an electric light taken through this sheet of black ebonite. It is perfectly opaque to all visible radiation, but through it those rays which are below the red can penetrate to a certain extent. You see then we are able to photograph with the dark rays, absolutely without using the visible rays at all. Another example of this might probably be interesting for you to see, and that is this: it is an experiment I carried out to-day, so that it is fresh in my memory. Here I have a card pierced with a few holes. That card was taken and laid very nearly, but not quite, in contact with this blue bromide film, and over it was placed a blackened kettle of boiling water. If those dark rays had any effect on the blue bromide, the radiations from the kettle of boiling water ought to alter the salt. Let us see whether it did so. The photograph is rough, but still I daresay it is specific enough to show you the result. You will see that the images of these holes are exactly reproduced, and the source of illumination, if it may be so called, was the kettle of boiling water, the radiations of which sufficed to cause an alteration in the silver salt. I have been able once—I have not tried to repeat the experiment—to photograph a kettle of boiling water by its own radiation; that is to say, it became a source of light.

We will next appeal to the spectrum to see whether it is sensitive to all the radiations, and I think you will find that it will answer our expectations to the highest degree. I have on the screen the first photograph of the prismatic spectrum which was taken with this salt. You will be able to note the position of the spectrum with regard to the blue, the green, the yellow, the red. Below the impression made by the latter we have the famous A line, and below this again we have an impression made by the infra-red rays. What we next attempted was of course to get better photographs than the one I have already shown you; and next to draw a map of the prismatic spectrum.

In the following diagram we have the results of the measurements of these photographs. You see to what an enormous extent the solar spectrum extends below the limit of the visible spectrum—the A line is seen with great difficulty in the spectroscope (Fig. 7). The last band in the photograph that I last showed you was the band marked τ, but below that there are other bands which I was subsequently able to obtain. It is very rarely that these bands can be photographed at all, not because the plate is not sensitive to those radiations, but simply because of the atmospheric absorption which cuts off these particular radiations and prevents them from reaching our earth. I may say that the theoretical limit of the prismatic spectrum is very nearly reached here—not quite, but nearly. Cauchet showed that if you set up along the length of the spectrum, as we have it here, the inverse square of the wave-length of any two lines, say the inverse square of the wave-length of the B line, and erected a perpendicular line of a length representing that particular number, and also of the wave-length of the F line say in the same way, and then joined of the points thus obtained, we should get a line on which the inverse squares of the wave-lengths of H G C D would lie, and also theoretically the wave-lengths of lines below the red. Thus if we took and joined two points, all the other inverse squares of the wave-lengths would lie along that line, very nearly. In that way a theoretical limit of the prismatic spectrum can be obtained; in other words, the prismatic spectrum must stop where the wave-length is infinity. You will see that in this diagram we very nearly reach the theoretical limit. Where there is no atmosphere to interfere with the radiation, it would be easy to reach it. Since the spectrum we photographed is the solar spectrum, between the slit and the source of radiation many miles of atmosphere with more or less aqueous vapour intervene, which prevent us obtaining the limit; but with the electric light the absolute limit can be reached on some occasions, though with some difficulty. It may be asked if we can assume that there is a practical as well as theoretical limit of the prismatic spectrum: and in answer to this I may say that the measurements made from other photographs, to which reference will be made, will demonstrate that one is fully justified in adopting the theory.

The disadvantage of using the prismatic spectrum for measurement is this: you will notice the waves are very much compressed as you get down towards the red. The ordinates to the curve (Fig. 7) represent the wave-length; and if you calculate the wave-lengths from the inverse squares given by the nearly straight line it forms a curve like the above.

Now owing to the compression of the ultra-red it was very difficult to decipher the full meaning of the impressions obtained

in this ultra-red region, more particularly as regards the resolution of bands into lines. You saw there were very few lines apparently, but there were bands, and the question asked was, Could we resolve these bands into lines? You recollect that Draper had in his photograph three lines below the limit of the red end of the spectrum taken by the oxidising process. They did not go very far down as it turned out, but still, there they were, and I think I can show you that those lines and bands are resolvable into lines. To do that, of course, we have to use a diffraction grating. On that stand I have a diffraction grating similar to the one Mr. Lockyer showed you, which was used in all the researches on the spectrum. We have on the screen the spectra produced by the grating; you will see that even the first two which lie next to the bright central image of the slit are much feebler than the spectrum you ordinarily see on the screen, as Mr. Lockyer pointed out. If you turn the grating further round you will see that another spectrum comes on, and by turning it still further we get a third, and so on. They are all feeble, but the two last very feeble indeed, but still they are present; of course by turning the grating in the other direction we should get similar spectra on the other side of the central image of the slit. By holding the screen up rather closer to the source of light, we shall be able to see the spectra better. I want you to notice that the violet of the third spectrum overlaps the red of the second spectrum. In order to photograph the ultra-red of the first spectrum it was necessary to use some artifice to cut out those invisible rays which lie between the violet and the red, and belong to the ultra-violet of the second spectrum, and also the violet and the blue, and the green of the same spectrum. In order to do that we used various absorbing media, but the most practicable for the purpose we had in view was a solution of bichromate of potash in water of about 1-25th of an inch in thickness. You will see that bichromate of potash cuts off the violet and the blue, and leaves the red and yellow intact. This solution was used with the diffraction spectrum to photograph the ultra-red regions. I will throw a diagram on the screen to show the overlapping of the different spectra, to make it more clear. You see in the second order the H lines comes a little beyond A (Fig. 8), and in the third line they come as far as the

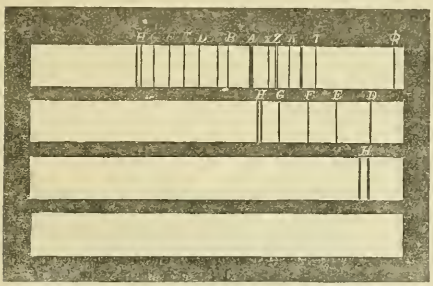

FIG. 8.—Overlap of the diffraction spectra of the 1st, 2nd, 3rd, and 4th orders.

D line. You will also notice that the bichromate of potash cuts off certain rays in the first order-spectrum, the same rays of the second-order spectrum, and those also in the third-order spectrum.

I will now throw on the screen some photographs taken with this diffraction spectrum [shown and explained].

That is as far as we have been able to distinguish with the diffraction grating up to the present time, although we have hopes that with more labour we shall be able to get further down, not to the theoretical limit of the spectrum as shown by the diffraction grating, since that is infinitely far down, but at all events towards that way. In order to show how we can plot the wave-lengths it is only necessary to use the same plate of green bromide and to expose half the slit to the second-order spectrum for the blue end, and the other half to the first order of the red end of the spectrum, using, of course, proper absorbing media. In this photograph we adopted this artifice. The top half of the slit was exposed to the red end, and the bottom half to the blue, and so you see two spectra superposed one above the other (Fig. 9). Now we know that in the second order the wave-length of a line will be exactly half that of the wave-length of the next order which is above it. That is to say, suppose the wave-length of the H line to be 3900, the ultra-red ray which lies over it would be exactly 7800, and so on. By these means, by the coincidences of these lines one with the other, one is able to ascertain the exact wave-length of lines which lie in the ultra-red rays of the spectrum.

Then came the question, were we able to separate Draper's lines into bands, and were we able to separate these bands which

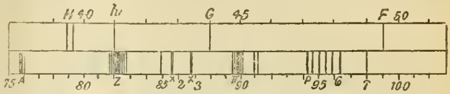

FIG. 9.—Method of determining the wave-lengths in the supra red region.

we photographed into lines? Draper's three lines were separated into 250 distinct lines, and the bands on the screen into somewhere over 500.

Having obtained means of photographing in the ultra-red region of the spectrum, what was the natural use to make of it? To introduce it into the photographic art? Not so, because there were considerations which prevented our doing so; but it seemed that there were other problems which might be settled very readily by recourse to another investigation. It seemed probable that colourless liquids ought to exercise absorption in the ultra-red regions. Nothing was known regarding them beyond the remarkable and well-known experiments made by Prof. Tyndall with a thermopile, with some source of radiation at a comparatively low temperature. He used a red-hot platinum spiral or a cube of hot water, and noted the radiation which was allowed to pass through different liquids and gases. But the knowledge obtained by this method was very much the same as if we were told that so much total visible light was cut off when examining the absorption spectra of coloured bodies. No definite knowledge was obtained as to the parts of the spectrum where the absorption of the liquids took place; in other words, Tyndall gave us a notification of the absorptions, and not their locality—a most important point.

Col. Festing joined with me in investigating this question, and we commenced, as might naturally be expected, by testing the absorption spectrum of water, and then we went on to a variety of hydrocarbons, such as the alcohol series, benzine, and so on. I need not recount to you all the various difficulties we found in our way; they were varied, but ultimately we were able to overcome them. Early in our work we had glimmerings of the truth that subsequently burst upon us in its full and truest light. The method we adopted was as follows:—You may imagine a source of light—the positive pole of the electric light forms a very brilliant source when cast by a lens upon the slit of the photo-spectroscope (Fig. 10). A tube of liquid, T, was placed between

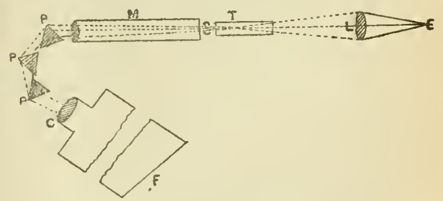

FIG. 10.—Apparatus used in photographing the absorption spectra of liquids.

the lens and the slits: the rays were passed through prisms P, and eventually were received on the photographic plate F such as we have here. Passing sunlight through the top half of the slit, and then using the electric light to get the absorption spectrum of the liquid through the bottom half of the slit, we were able to compare either the solar spectrum with the absorption of the electric light after passing through any liquid; or by placing two different liquids before the top and bottom half of the slit we were able to compare their absorption spectra with each other.

Some of the first results we obtained were with hydrocarbon

containing oxygen. Alcohol and ether are both hydrocarbons—they contain hydrogen, carbon, but also oxygen; and we noticed that in these oxygen compounds these bands of absorption were shaded bands, and not sharp and defined, as it were. We then went on to another series of compounds, or rather, part of the same group which contained no oxygen at all. Thus we worked with methyl iodide, ethyl iodide, and propyl iodide, and we found a very marked difference between the two spectra. We found that in the cases where there was no oxygen there were no shaded bands—that is to say, that if there were bands, they were sharp bands without shading at the sides (Fig. 11). What was the signification of this?

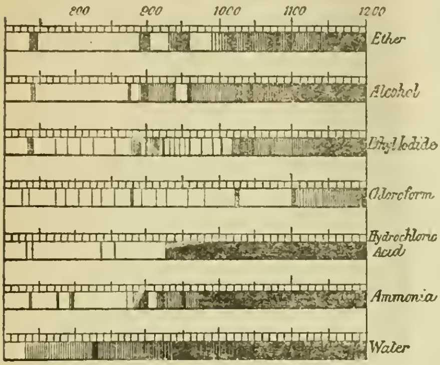

FIG. 11.—Absorption spectra of hydrocarbons, &c.

There must have been some meaning in it. Were the lines or the shaded bands due to carbon or to hydrogen? The lines could not be due to oxygen, because they were not present when oxygen was present. To what, then, could they be due? They must be due to carbon, hydrogen, or iodine; and which of these it became important to ascertain. In Fig. 11 we have a map of a selection of the different alcohols and the iodides, which were photographed. You will see that what I have said about alcohol is correct; that we have the shading off of the bands in the case of the alcohols. But when we come to the iodides we have a marked difference; we have lines springing up, as in ethyl iodide—distinct lines—which are also found in the other iodides. The question then was to trace these lines to their origin. If they were due to carbon we ought, of course, only to find them in carbon compounds; if they were due to hydrogen we ought only to find them where there was hydrogen. So we tried a series of substances, the absorptions of which I throw on the screen. When we tried chloroform, which contains only one atom of carbon and one of hydrogen, but three of chlorine, the whole spectrum became one of lines, nothing else but lines. These lines might be due to the carbon and hydrogen, or they might be due to the chlorine; so the next substance we tried was hydrochloric acid, which contains only hydrogen and chlorine. Here we have lines again which were coincident with some of the lines in the chloroform: those lines might still be due to hydrogen or chlorine. The next substance we tried was ammonia, which contains no chlorine, but three atoms of hydrogen and one of nitrogen. That gave lines again. We next tried carbon disulphide and carbon tetrachloride which contain neither hydrogen nor oxygen, with the result that we had neither bands nor lines. Evidently we had tracked the lines to their source; they were due to the oscillation of hydrogen in these particular compounds we had examined. When we took sulphuric acid we found the same result again; the bands were rather shaded, and to a certain extent it was the same in water also. The oxygen, as we shall see, formed these bands, but at the same time at the limit of the bands a distinct line was formed. Thus then we found in all the absorption spectra which contained lines, that those lines were due to hydrogen and nothing else.

I should next like to show you the further information we gained from these photographs. In the diagram we have the alcohol absorption spectrum, with a chloroform spectrum beneath it. The question to be answered is—Why should we have bands with sharp edges and fine lines in one case, and bands with sharp edges and bands shaded off in the other? In both cases the bands with sharp edges seem to be due to the base of the compound. Thus, in the case of the chloroform, the thick line or sharp-edged band seems to be due to the combination between carbon and hydrogen, and those other lines seem to be due to the vibration of hydrogen and nothing else.

What was the meaning however of the shaded bands as (say) in alcohol? When we came to the photographs it was found without exception that hydrocarbons containing oxygen, when not contained in the radical or base of the compound, always gave some shaded bands, and on measurement it was found that the shading always stopped at points where, in other spectra, we had marked the hydrogen lines. This coincidence was very remarkable, and could not be fortuitous; in fact, it seemed that there must be some connection between the position of these lines and the termination of the bands. The bands must be due to the oxygen in the compounds. What we eventually arrived at at last was this, that the oxygen blotted out the spectrum between two hydrogen lines; that is to say, if you look at it in one way, the oxygen oscillated between two hydrogen lines and cut out that particular portion of the spectrum. When we came to the benzine series, or in fact any other series, we found the same hold good: where we had hydrogen and no oxygen we had lines; where we had oxygen with the hydrogen we had bands. Where we had carbon, hydrogen, and oxygen, you see we had a shaded band and few lines; where we had carbon, hydrogen, and chlorine, or carbon, hydrogen, and bromine, or carbon, hydrogen, and iodine, or carbon and hydrogen alone, we had sharp-edged bands and many lines. Where we had carbon and chlorine, or carbon and nitrogen, or carbon and sulphur, we had no absorption whatever. That is to say, if you place bisulphide of carbon or cyanogen before the slit in one of these tubes we shall see no absorption take place except a general absorption. In other words, the absorption gradually increased and mounted up from the least refrangible end of the spectrum towards the blue end of the spectrum, and that was the only absorption which could be traced. The following table concisely shows the above:—

Carbon, Hydrogen, and Oxygen	Shaded band spectrum and few lines.
Carbon, Hydrogen, and Chlorine Carbon, Hydrogen, and Bromine Carbon, Hydrogen, and Iodine... Carbon and Hydrogen	Sharp-edged bands and many lines.
Carbon and Chlorine ... ... Carbon and Nitrogen ... ... Carbon and Sulphur	No special absorption.
Hydrogen and Oxygen	Bands and lines.
Hydrogen and Chlorine	Lines only.
Hydrogen and Nitrogen	Lines only.

The character of absorption then was general and special. Where we had special absorption bands they were due primarily to hydrogen *atoms* vibrating; whilst the general absorption was due to the *molecules*; the heavier the molecule the more it let the ultra-red through the spectrum. If bases of two series were present we found the absorption due to each base of these particular compounds present in the spectrum. Thus, by taking the absorption spectrum of, say, a compound of ethyl and benzine, we are able to say that the ethyl base was there and the benzine base was there also; the bases of these particular series being denoted by these thicker bands with sharp edges to which I have already referred.

Thus then spectrum analysis opened a way for the chemical analysis of these organic compounds, not of course in their entirety, but so as to get a qualitative idea of what they may contain.

The length of liquid generally employed was six inches, and the natural question to ask is, What is the difference caused by increasing or diminishing the thickness of the liquid between the slit and the source of light? If you increase the thickness of the liquid between the slit and the source of light, it is this: Where you have oxygen bands you have them shaded off; increasing in intensity, but spreading further—they do not spread further in a nondescript way, but in a very marked manner they spread out to the next hydrogen line, and so on. Therefore, supposing with a very small thickness we have oxygen bands extending between two hydrogen lines, in the next six inches of liquid the

absorption will cover three hydrogen lines, and so on. Where you have lines, the lines never alter; where you have those base bands, or radicle bands, as they are called, they never alter; they are always in the same position, and never spread out or diminish either to the right or left. When you diminish the thickness of the fluid those bands are always present, and they are the last things to disappear in the absorption spectra.

Another remarkable thing with regard to these compounds is, as a rule there are two bands which are characteristic of their base. There is a band which is nearly always situated near the limit of the red, and another between wave-lengths 8000 to 11,000. That is to say, there is always a band to be seen somewhere about "a," and another somewhere about ρ. Those are characteristic of any particular compound we may have present.

You may say that I have been giving you a lecture on chemistry but in reality it is one which I hope may lead to results in solar physics. And I now venture to tell you how (Fig. 12). Here

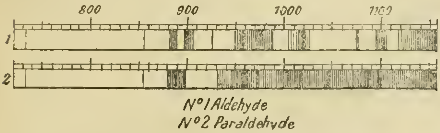

FIG. 12.—Absorption spectra of aldehyde and par-aldehyde.

is a pair of bodies which we examined, to which I wish to draw your particular attention, namely, the spectra of aldehyde and par-aldehyde. Now aldehyde and par aldehyde are the same bodies exactly in composition, only chemists tell us that par-aldehyde has three molecules of aldehyde in its one molecule—the only difference then between them is that there are three molecules of aldehyde combined to form par-aldehyde; aldehyde of course being one molecule by itself. Not only do chemists tell us that this is the case, but they know it, because if they heat par-aldehyde they get aldehyde formed again, and can reconvert this into par-aldehyde. Now I want you to notice the difference in the spectra between these two bodies. We have two bodies of the same chemical composition and of different molecular grouping, and you will see there is a total distinction in the two absorption spectra they yield. The only thing in common is the radical band. There may be one or two other coincidences, but all the rest of the spectra are perfectly distinct. Now if you refer back to Mr. Lockyer's lectures I think this alone will throw some light on what he has already said to you. He has told you, for instance, that the spectrum of iron in the flames and the spectrum of iron in the

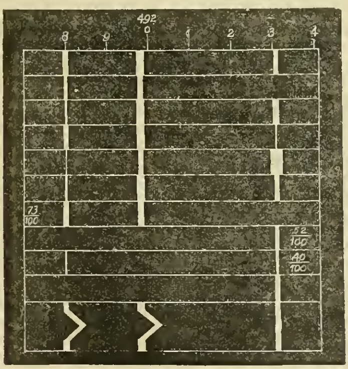

FIG. 13.—[illegible] three iron lines as observed by Lockyer.

spots are dissimilar; and he has kindly furnished me with a photograph which shows one little part of the spectrum in which this is exemplified in a remarkable degree. In it we have three iron lines close to one another (Fig. 13). In the sun-spots two of those only appear, and in the flames the third alone appears. If you look at this by the light of that photograph of aldehyde and par-aldehyde which I had on the screen, I think it is a reasonable deduction to make that the iron in the flame and that in the sun-spots have different molecular groupings. I say that this spectral analysis to which we have subjected aldehyde and par-aldehyde, and many other similarly constituted bodies, lends confirmation to that view. Of course, in the case of organic compounds, we can appeal to the chemist to analyse them for us, and he tells us that they are different molecular groupings. It is scarcely fair in one case to admit that the two spectra are given by two molecular groupings of the same substance, and in the other to deny it.

Again, we found that many lines were common to each hydrocarbon: thus we found a line at 867 of the scale, common to benzine and to alcohol; and to take one particular case, we found a special line common to water, hydrochloric acid, and chloroform. Has this any bearing on what you have heard? Mr. Lockyer has told you that some short lines are to be found in two, three, four, or even six different metals, not taking the long lines into account, as they might be considered to be due to impurities in the different spectra. Let us apply this to our case. A certain substance, A, has certain lines coincident with B; B also has certain lines coincident with C; and C also has other lines coincident with A. Now we will suppose these hydrocarbons were looked upon as elements, but that eventually the chemists split up what they considered elements, and found that the only substance which was common to the three was hydrogen. I leave you to draw the parallel between Mr. Lockyer's experiments and those which I have endeavoured, in a very rough and unsatisfactory manner, to bring before you. I think, if the chemist will admit that in the case of the hydrocarbons it is hydrogen which produces the lines common to all, there is no reason on earth, supposing the metals are not elements, why you should conceive that they should not have a common constituent in the same way that the organic compounds have a common constituent in the shape of hydrogen. I leave that for your consideration.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—Among the professorial notices of next term's lectures already published are those of the Professors of Astronomy, Geology, Botany, and Medicine.

Prof. Pritchard will give three courses at the University Observatory. He will lecture on the Lunar and planetary Theories, and will form two classes for practical instruction in the evenings. Prof. Prestwich will lecture on Stratigraphical Geology in the University Museum. Prof. Lawson will lecture on the Elements of Systematic Botany at the Botanic Garden.

The Professor of Medicine, Dr. Acland, gives notice that the next examination for a Radcliffe Travelling Fellowship will commence in the second week of February. Candidates are requested to communicate with the Professor.

The professors and lecturers engaged in teaching Physics have settled a combined system of lectures for next term as below:—

Hydromechanics, by Prof. Price; (1) Distribution of Terrestrial Magnetism, (2) Electricity developed by Contact of different Substances, by Prof. Clifton; Instruments and Methods employed in Optical Measurements, by Prof. Clifton; Practical Physics, by Prof. Clifton, Mr. Stocker, Mr. Heaton; The Generation and Measurement of Electric Currents, by Mr. Baynes; Electrostatics (treated Mathematically), by Mr. Hayes; Elementary Mechanics (treated Experimentally), by Mr. Stocker; Problems in Elementary Mechanics and Physics, by Mr. Heaton; Elementary Physics treated Experimentally (Heat and Light), by Mr. Dixon. The lectures on Optical Instruments are intended to serve as an introduction to the practical work in the laboratory. The last three courses of lectures are intended to meet the requirements of candidates for the Preliminary Honour Examination.

An examination for a Fellowship in biological subjects will be held at University College in February, 1882, beginning on Wednesday, February 22, at 9 a.m. Candidates are desired to call on Mr. C. J. Faulkner with the usual testimonials and certificates on Tuesday, February 21, between 5 and 6 p.m. But intending candidates are desired to send in their names to him before February 1, 1882, with a list of the subjects which they offer for examination, and at the same time to mention any branch of biology to which they have turned special

attention, or on which they may have written original articles. Copies of any such articles should also be sent in. The examination will comprise (A) Papers of Questions, and (B) Practical Work, in Zoology, Physiology, and Botany. Further and more detailed information may be obtained of Mr. Faulkner.

CAMBRIDGE.—Prof. Stuart has received the offer of an engine from Dr. Siemens for his class-rooms of mechanism. The extension of the workshops is to be proceeded with at once.

Practical anatomy will commence next term on January 20. Demonstrations on Heat, by Mr. Glazebrook, and Electricity and Magnetism (advanced), by Mr. Shaw, will be given next term in the Cavendish Laboratory.

Mr. Garnett will give elementary lectures on Heat in St. John's College, beginning February 2, adapted to the 1st M.B., the Special Examination in Mechanism and Applied Science, and the first part of the Natural Sciences Tripos.

GLASGOW.—The Clark Fellowship in Natural Science (225*l.* per annum for three years) has just been awarded to Mr. John H. Fullarton, M.A., B.Sc.

SOCIETIES AND ACADEMIES

LONDON

Chemical Society, December 15.—Prof. Roscoe, president in the chair.—The following papers were read:—On some higher oxides of manganese and their hydrates, by W. H. Veley.—On a new alkaloid from Cinchona bark, by D. Howard and J. Hodgkin. The authors have extracted from the bark of China Cupræa an alkaloid closely resembling quinine in its general properties. It differs in the solubility of its salts; and from the readiness with which the alkaloid crystallises from ether; they have named it homoquinine. In the discussion which followed this paper Mr. Cownley mentioned that he, in conjunction with Dr. Paul, had separated apparently the same alkaloid, and that the results would be published in the next number of the *Pharmaceutical Journal*.—Contributions to the chemistry of the rare earth metals, by B. Brauner. This paper gives an account of a most thorough investigation of some compounds of cerium and didymium, and the determination of the atomic weight of lanthanum. The author has prepared a tetrafluoride of cerium and a pentoxide of didymium; he places these metals in the eighth series (horizontal) of Mendeljeff's system, thus: Cæsium 133, barium 137, lanthanum 139, cerium 141·6, didymium 146·6.

Royal Horticultural Society, December 12.—Lilies attacked by larvæ of *Brachycerus*, sp.: Mr. Maclachlan exhibited larvæ received from Mr. G. F. Wilson of Weybridge, which eat into the centre of the bulbs of lilies.—Cocoanut attacked by larvæ of *Hylocætus*, sp. The same gentleman also showed some remarkable larvæ with a curiously indurated joint below the head. The species, he observed, was remarkable in penetrating the soft wood of palms, as the European species attacks hard wood, such as firs. He had met with the latter in the Black Forest.—Proliferous fir cone: Dr. M. T. Masters exhibited a cone of *Abies Douglasii*, in which the bracts were foliaceous, but the seed-scale partially atrophied, as is usually the case in proliferous cones. He contrasted this with a proliferous state of *Sciadopitys verticillata* (see Veitch's "Manual of Coniferæ," Fig. 46), in which the seed-scale became foliaceous, the bract remaining normal. The importance of this latter specimen in relation to the nature of the so-called leaves of *Sciadopitys* and of the seed-scale of the Abietineæ was commented on.—Embryo-bud of oak; Mr. W. G. Smith exhibited a specimen about one and a half inches in diameter. It was removed from beneath the bark. Such are extremely common in beeches, in which they vary from the size of peas to that of one's fist.

Society of Telegraph Engineers and of Electricians, December 15.—Annual general meeting.—The following gentlemen were elected as the council of the Society for the ensuing year:—President, Lieut.-Col. C. E. Webber, R.E.; Vice-presidents:—Willoughby Smith, Prof. W. G. Adams, F.R.S., C. E. Spagnoletti, M. Inst., C.E., Prof. D. E. Hughes, F.R.S., Hon. Treasurer, E. Graves; Hon. Secretary, Lieut.-Col. Frank Bolton; Council: W. S. Andrews, William T. Ansell, Sir Charles Bright, M. Inst. C.E., C. B. Bright, the Earl of Crawford and Balcarres, F.R.S., H. G. Ericksen, H. C. Forde, M. Inst. C.E., Matthew Gray, John Fletcher Moulton, F.R.S., Alexander Siemens, Augustus Stroh, C. F. Varley, F.R.S.; Associate Members of Council: Capt. J. T. Bucknill, R.E., C. H. B. Palen, T. R. Crompton, M. Inst. C.E.

EDINBURGH

Royal Society, December 5.—The Right Hon. Lord Moncreiff, president, in the chair.—After a few introductory remarks, the president proceeded to read the obituary notices of Dr. J. Hill Burton, Dr. Andrew Wood, Prof. Sanders, Dr. Handyside, and the Rev. Dr. Cumming.—A quaternion paper on Hamilton's symbolical cubic, by Dr. Gustav Plarr, was presented by Prof. Tait, who then made an interesting communication on the subject of Mirage. By means of a simple assumption as to the law of variation of density in a stratum of air near the earth's surface, a complete explanation could be given of the very curious erect, inverted, and again erect images which were observed by Vince towards the end of last century, and formed the subject of the Bakerian Lecture of 1799. The necessary geometric conditions fulfilled by contiguous rays so as to give either an erect or an inverted image are well known; but no attempt had been made to imagine a simple state of affairs which would give *both* images at once. If the refractive index of a portion of a medium is given by the equation $\mu^2 = a^2 + y^2$, where y is the distance of the portion considered from a given plane—the plane, namely, of minimum density, then it can be easily shown by Hamilton's general method that the path of any ray which is deflected without touching the plane of minimum density is a distorted inverted catenary, and is obviously symmetrical with respect to a vertical line through its vertex. Whatever the law of density, the upper of two such contiguous rays emanating from a given point must in general have its vertex either a little behind or a little in front of that of the lower ray. In the former case the rays *cross* before they return to the same level from which they started, and an inverted image is the consequence; in the latter case they do not cross, and the result is an erect image. Hence the mere inspection of the locus of vertices of all possible rays coming from a given point is enough to tell the kind of image seen by any given pencil of rays belonging to the system. Also all rays that pass between any two given points on the same level must have their vertices on the vertical line half way between these points. If then the locus of vertices is such that it can be cut in three distinct points by a vertical straight line, evidently three images will be possible, two direct and one inverted, precisely as seen by Vince. That under certain circumstances the locus is of this nature can easily be demonstrated. It is not essential that the alteration of refractive index should extend through a large stratum of air; indeed the supposition that it holds only through a limited stratum, and that below the air may be of practically uniform density, gives results much more in accordance with what has been observed in nature.

SUICIDE

Suicide; an Essay on Comparative Moral Statistics. By Henry Morselli, M.D., Professor of Psychological Medicine in Royal University, Turin, &c. International Science Series, Vol. xxxvi. (London: C. Kegan Paul and Co., 1881.)

THIS work enters the International Science Series as an abridged translation of the author's original book, which was written in Italian. As its title implies, it is throughout statistical, and as no pains have been spared in collecting statistics from every available quarter, the results are the most comprehensive and complete that can be obtained with reference to the subject of which the essay treats. These results are interesting, not only because of the light which they shed upon a somewhat sombre topic, but also because they show what a powerful and trustworthy instrument of inquiry we possess in the statistical method, even when applied to what at first sight might appear the most complex and variable of causes leading to the most uncertain or least calculable of effects. For assuredly the most striking feature common to all the multitudinous tables which Dr. Morselli presents to us is the uniformity with which, under a given set of conditions and over a sufficiently wide area of observation, a certain average number of suicides will occur.

Chapter I. is on "The Increase and Regularity of Suicide in Civilised Countries," and it shows that, to use the words of its opening sentence, "from statistics collected up to this time is demonstrated this most painful fact, that suicide has increased from the beginning of the century, and goes on continually increasing in almost all the civilised countries of Europe and of the New World." Thus, for instance, in France from 1827 to 1852 there was a continued increase in the annual number of suicides, from 48·0 to 82·6 per million of inhabitants; and in Italy from 1864 to 1877 there was a similarly gradual rise from 29·2 to 40·6.

Of the "influences which act upon suicide," the first that are considered are the "cosmico-natural." Concerning climate it is shown that "the South of Europe gives the minimum proportion, while that rises by degrees as the centre is approached, reaching a maximum at 50° of latitude, and again gradually declining northwards; "whence it appears that the zone in which are situated the countries where suicide is most frequent is the *temperate*, as might be anticipated from the historical fact of the favourable development of ancient and modern civilisation in the regions furthest removed from the extreme climates." As shown graphically by a shaded map, "the line of suicide crosses the European continent from the north-east to the south-west."

The distribution of suicide in each of the chief countries of Europe is then given. Of the statistics on this head we may quote those which have reference to our own country.

"In Great Britain the average, lowest in Ireland, higher in Scotland and Wales, becomes still more elevated in the North of England, and it acquires its maximum in the South; nor can it be said that this is caused by the

metropolis, as it was in France by the irradiation of Paris, because London, on the contrary, gives a smaller proportion of suicides than some of the South and Southwest counties, and especially Cumberland. We give in Table VII. the averages of the five years 1872-76 calculated on the population of the census of 1871.

TABLE VII.—*Distribution of Suicide in England-Wales (1872-76)*

Divisions and Counties.	Annual average.	In the million.
I. London.		
Middlesex	199·4	88·6

XI. Welsh.		
42. Monmouthshire...	10·2	46·4
43. South Wales ...	33·6	43·8
44. North Wales ...	16·0	36·7

Why Cumberland, Sussex, Surrey, Warwick, and most of all Rutland, should show such pre-eminence is unaccountable.

Other things equal, the most favourable localities for suicide are flat plains and the courses of large rivers, while mountainous districts invariably yield the smallest percentage. Again, "the regions where suicide predominates are all those formed by alluvial deposits of the more recent epochs; regions, that is to say, which up to the Tertiary period had remained covered by the sea, and which, emerging only in later times, assisted the development of the more recent flora and fauna."

Concerning the influence of seasons, it is shown that—

"The transition period between spring and summer, and especially the month of June, exercises the most positive influence on suicidal tendency, whilst that of winter, particularly of December, would be negative. It is strange that for long an opposite opinion was held; it was maintained that suicide was more frequent in damp, cloudy, and dark weather, such as helps the development of the melancholy passions."

On this subject Dr. Morselli observes that the regular distribution of voluntary deaths in the course of the year, which, taking the chief countries of Europe, he graphically represents by means of curves, "is in evident relation with that of madness. All alienists are agreed as to the greater frequency of mental alienation in the summer season, and this law is confirmed by all the statistics of the asylums for the insane." But—

TABLE XIII.—*Synopsis of the Ethnological differences of Suicide*

	Races and Stocks.	Countries.	Population.	Annual number of suicides.	Per million.	General average.

"It is to be noted that suicide and madness ***are not influenced so much by the intense heat of the advanced summer season as by the early spring and summer, which seize upon the organism not yet acclimatised and still under the influence of the cold season.*** And this also applies to the first cold weather, as may be seen in the proportional figures of our statistical tables, perhaps better still in the second elevation, which all the curves, as shown by us, offer in the autumn months of October and November, when the change from the warm to the cold season is more severely felt by the human constitution, and especially by the nervous system."

It is a curious fact that everywhere suicides are committed with greater frequency during the first third of any given month than during the second third, and during the second third than during the remaining third. Moreover of the first third, the first two days yield the largest proportional number. "From whence this fact proceeds is not clear, unless it be that in the first days of each month debauchery, dissipation, orgies, especially in large cities, are more numerous."

Again, among men the first days of the week predominate in respect of influences leading to suicide over the later—the order standing Tuesday, Thursday, Monday, Wednesday, Friday, Sunday, Saturday. Among women, however, an inverse ratio obtains—the order here being Sunday, Friday, Thursday, Wednesday, Tuesday, Saturday, Monday. Doubtless the reason of this among men is that Saturday is usually pay-day, and "thus a day of joy, of material well-being, of moral quiet." This lasts through Sunday, but with Monday men's labour begins, with the after effects of satiated gluttony, inebriety, &c. On the other hand, "the high proportion [of suicides] among women on Sunday is of the greatest psychological interest."

As regards the time of day, the hourly distribution of suicides—

"Is parallel to activity in business, to occupations and work, in short with the noise which characterises the life of modern society, and not with silence, quiet, and isolation. Petit and De Boismont then justly note that the influence of the diurnal hours is shown also in the predominance of those months which have the longest days, and are precisely, as we see, June, May, and July. Thus all the influences which we are studying join together and mingle in one single and efficient synthesis, that is to say, the dependence of man upon nature."

One of the most interesting chapters in the book is that on "Ethnic Influences," a general summary of which is given in the appended table.

On this it is remarked :—

"The low position in point of numbers held by the English peoples, with regard to suicides, in comparison with the Germanic, whilst the first place in the civilised world as regards power and riches belongs to them without dispute, is astonishing; it is not modern Rome, it is not England, which gives the greater number of suicides."

And the divergence between England and the countries where the Celtic race remains most pure (Scotland, Ireland, Wales), proves "the influence of the Germanic element infiltrated"—the Celtic races being least addicted to suicide, and the Germanic most so.

Another very interesting section is that on religious influences. The Jews display "an habitual resistance to suicide, though the same cannot be said with regard to madness." Again, "the Catholic nations, Italy, Spain, and Portugal, stand on the last step of the scale of suicide, whilst those exclusively or mostly Protestant, take the first grade; it suffices to cite Saxony, Denmark, Scandinavia, and Prussia. In countries of mixed religions, the inclination towards suicide diminishes in direct ratio to the predominance of Catholicism . . . the most frequent order in which the various religions follow each other is thus: *Protestants, Catholics, Jews;* and the next in order of frequency come *Protestants, Jews, Catholics.*"

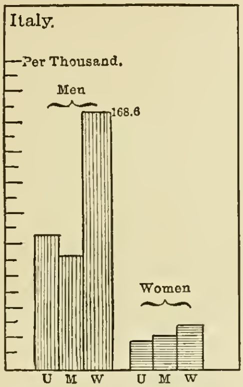
In this connection the following is perhaps worth quoting :—

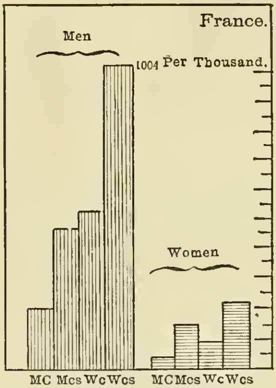
"The very high average of suicides among Protestants is another fact too general to escape being ascribed to

the influence of religion. Protestantism, denying all materialism in external worship and encouraging free inquiry into dogmas and creeds, is an eminently mystic religion, tending to develop the reflective powers of the mind and to exaggerate the inward struggles of the conscience. This exercise of the thinking organs which, when they are weak by nature, is always damaging, renders them yet more sensible and susceptible of morbid impressions. Protestantism in the German States further exercises this exciting influence on the cerebral functions in yet another manner; it originated those philosophical systems which are based on the naturalistic conception of human existence, and put forward the view that the life of the individual is but a simple function of a great whole. These philosophical ideas are harmless enough to strong minds and those stored with a fit provision of scientific culture, but in the democratic atmosphere of our times the heart is not educated *pari passu*. The religious apathy with which the present generation is afflicted does not arise from a reasoned inquiry into the laws of nature or a scientific appreciation of its phenomena; it is not in short a deep conviction of the mind, but springs from a physical inertia and from the little hold obtained by any ideas but such as are directed to material improvement and the gratification of ambition. To our mind therefore the great number of suicides is to be attributed to the state of compromise which the human mind occupies at the present time between the metaphysical and the positivist phase of civilisation, and as this transition is more active in countries of marked mystic and metaphysical tendencies, such as is the case with Protestantism, it is natural that in them suicide should have the greatest number of victims."

Another feature of interest which a comparison of the statistics of all countries brings out is that "it is those countries which possess a higher standard of general culture which furnish the larger contingent of voluntary deaths,"—a fact which finds its curious expression in the following:—"The scale of these countries according to suicide is nearly the same as that of the periodical press." It is likewise higher in towns than amongst the more scattered inhabitants of the country.

Concerning sex, "in every country the proportion is one woman to three or four men, as in crime it is also one to four or five"—a proportion which the tables show to be everywhere maintained with wonderful constancy, save in a few cases, the most remarkable of which is that of





Spain, where "one woman commits suicide against only two and a half men." This strong tendency towards suicide shown by the women of Spain our author attributes "to the force of their passions, which brings them nearer to the male sex."

In both sexes the suicidal tendency augments in direct ratio with age up to the fifth decennial period for men, and up to the fourth for women, beyond which they diminish with as much uniformity. In England, however, the number of young women who commit suicide between fifteen and twenty years is so large as to exceed by more than a tenth the number of men. This "precocity of suicide in English women lasts up to the thirtieth year, when the proportional relation between the two sexes becomes nearly equal to the average. The masculine excess also seems to diminish in extreme old age, so that at above seventy the two sexes tend to draw near again." But—

"The diminution in the last period of life is much more irregular than in all the other conditions: strongest in Würtemberg, less so in Sweden, Belgium, and England; very weak in France, Bavaria, and Italy; failing almost entirely in Denmark (1835-44), Saxony, Austria, and perhaps Prussia. This diminution of suicide amongst the old belongs to the weakening of their character and to that want of energy natural to the last period of existence, in which man returns almost to childhood, and not having a long future before him, and even if overtaken by misfortune, he prefers to await the natural end of his days. Moreover, the religious sentiment awakens and revives in old age, acting as a curb to the passionate emotions and as a supreme comfort in adversity."

The remarkable effects of marriage, widowhood, and presence or absence of children may be best appreciated by transcribing one of Dr. Morselli's diagrams, where U. means unmarried, M. married, W. widowed, MC. married with children, MCS. married childless, WC. widowed with children, and WCS. widowed childless.

A number of tables are given showing the effects on suicide of different occupations. "First of all are the literary, scientific, journalists, engineers, geometricians, all those, in short, who make the greatest use of their brain power. Next come the military, of whose very high

inclination towards suicide we shall speak in the following section; and then the true professionals, tradespeople, and all those reckoned in the vagrant professions." The statistics with regard to the military are remarkable. Thus in Prussia the average suicide over the whole male population is 394 per million, while in the army it rises to 600 or 620. In Austria the proportion is still higher, viz. 866 per million as against 122 of the civil population, and in the Belgian army the case is nearly as bad. In the English army from 1862-71 the suicidal tendency was more than triple that of the male civilian population. "This tendency, moreover, augmented as time advanced; from 1862-71 it grew from 278 per million to 400, and even reached 569 in 1869. The tendency increases with the sending away the troops from Europe, so that in the kingdom (*at home*) the number is 339 per million, but in the English possessions in India it rises to 468." Of the different sections of the British army members of the cavalry are most addicted to suicide (in one year the percentage among the dragoons being as high as 785 per million), next the artillery, then the infantry, foot-guards, engineers, and lastly the household cavalry.

Analysis of the motives which lead to suicide shows this as a general result:—"In man the manifestation of personal interest rules in [almost] every case, and as only a fourth or fifth of the suicides are committed by women, the already small proportion of those which are due to noble and generous motives becomes still more attenuated."

Concerning the methods and places chosen by suicides,

"Each country certainly has its peculiar predilections, but in the aggregate of the peoples by whom suicide is practised, the rope appears to be chosen before every other instrument, and immediately after that water (both giving 5-10ths to 8-10ths of cases); firearms follow; then those arms which cut or stab; falling from a height is preferred to charcoal and poison; and lastly come all the other means."

Hanging stands in inverse ratio to drowning. For in Italy and other countries where hanging is most rarely resorted to, drowning is most common, while in Russia, where hanging is the favourite mode (four-fifths of all the suicides) drowning is very rare (hardly 6·9 per cent.). Firearms are preferred in the South of Europe and by the military everywhere, while in England poison and throatcutting are most favoured. It is curious that "there is a constant difference between the sexes in falls from heights and crushing under railway trains, the former being proportionally more frequent among women, the latter, on the contrary, much more so amongst men." There are other "sexual divergences" of the same kind, and as showing the combined influence of sex and age we may quote one other passage:—

"Males under 15 years of age choose hanging (86 per cent.), and women choose drowning (71 per cent.); in the ages between 15 and 20 the same predilection of the two sexes continues, but it lessens (hanging amongst males is 72 per cent.; drowning among women 65), and it grows still less between the ages of 20 and 30. With the diminution of the tendency towards hanging, that towards drowning increases amongst the men, the greatest number of deaths by this means falling between the ages of 40 and 50; but in advanced age the old people return to a preference for hanging, even more than children (91 per cent.)."

The book concludes with a short "Synthesis," which leads to the proposition that "Suicide is an effect of the struggle for existence and of human selection [*i.e.* natural selection operating in the human species], which works according to the laws of evolution among civilised people." From the present sketch it will be seen that the work as a whole contains many facts of interest to sociologists, although to the rest of the world its somewhat repulsive details will appear useful only as showing the practically emphatic answer which sundry classes of the community respectively give to the question "Is life worth living?"

GEORGE J. ROMANES

OUR BOOK SHELF

Catalogue of the Phænogamous and Vascular Cryptogamous Plants of Michigan—Indigenous, Naturalised and Adventive. By Chas. F. Wheeler and Erwin F. Smith. (Lansing: George and Co., 1881.)

THIS excellent contribution to the flora of the United States has been compiled at the suggestion of the State Horticultural Society of Michigan. It is prefaced with a list of the various catalogues, from that by Dr. Jno. Wright, embracing 850 species, and published in 1839, to that of Dr. Palmer in 1877. With reference to its flora the Peninsula may be roughly divided into two great divisions—the hard wood and the soft wood-lands—one representing the Appalachian flora, the other the Canadian. The hard-wood country lies south of latitude 43°, and consists of very fertile sand, clay, or loam, mostly cleared of the original forest and largely cultivated. The upper Peninsula has a much colder climate than that of the lower Peninsula, and its flora is in many respects decidedly northern. Pines, fir, cedar, larch, elms, poplars, maples, and birch, are among the principal trees; the proximity of the great lakes exerts a marked influence on equalising the temperature, and the effects thereof are well seen. Trees like *Liriodendron tulipifera*, *Cercis canadensis*, *Gleditschia triacanthos*, *Cornus florida*, and *Morus rubra*, which belong to Ohio and Central Illinois, have crept northward, favoured by the mild influence of the lake winds through the central and western part of the Lower Peninsula often beyond the middle. The flora as detailed shows 1634 species. The composites claim the larger number of species—182—about one-ninth of all. Sedges follow with 176 species; Grasses, 139; Rosaceæ, 61; Leguminosæ, 55; Scrophulariaceæ, 46; Umbelliferæ, 27. Of the 165 species of trees and shrubs about twenty are valuable for their timber. About twenty species of woody and herbaceous native climbers are frequent, and some seem worthy of cultivation. The arrangement followed is that of the fifth edition of "Gray's Manual," and a coloured map of Michigan is annexed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Pendulum Observations in London

THE reference by the President of the Royal Society in his recent annual address to the subject of contemplated pendulum operations permits me to assume that enough interest exists in those operations to render the offer which I now wish, with your kind assistance, to make, not altogether inopportune. I am now engaged in swinging pendulums, *in London*, under conditions

which enable me to invite any person who may wish to make themselves acquainted with the *modus operandi* by actual inspection, to come and witness the same. The only formality I would impose is the communication of the visitor's card and address, and a few hours' notice, in case the intended visit should promise to be inopportune. To reduce the likelihood of this I would intimate that the regular observations are made (in the present case) within about half an hour before and after the hours of six and twelve, morning, noon, evening, and midnight, during which the attention of the observer may be understood to be entirely preoccupied. At any other hour of the day or night, either I or my assistant will be desirous of explaining to the best of our ability whatever may be needful.

My reasons for making this offer so publicly are, in the first place, entirely scientific. I wish to give those who are curious on the subject a fair opportunity, and I hope to derive information or suggestions from those whose attention is for the time engaged in comprehending the details by means of which the general result is sought to be obtained. Beyond this, I am also desirous of obtaining some indications as to the degree of interest actually existing in England on the subject of gravity-measures of this kind.

The present site has a peculiar interest. It is a cellar which I have been lucky enough to find very near the desired spot—which is that which was occupied in the early part of this century by Kater, Sabine, Foster, and others; but was afterwards necessarily abandoned on the decease of Mr. Browne, of Portland Place, whose house was the *rendezvous* of those observers. It was in consequence of this abandonment that the intention was formed of founding a more permanent central point of reference; and as the establishment of a magnetical observatory at Richmond was at that time under consideration, the transfer of what may be called the English home of pendulum investigations from Portland and Tavistock Places to the new Richmond (or "Kew") Observatory was decided upon, and accordingly when next pendulum experiments were instituted, their site was in the Richmond Observatory. It is only recently, however, that the necessity of ascertaining the physical relation between the two sites has become a practical one.

Something of the same sort had been experienced in the earlier days, when, partly owing to Greenwich Observatory having formed the base or *point d'appui* on English soil, of one or two foreign series of operations; partly because of the obvious anomaly of having the principal English pendulum station in a private house; special observations were instituted for determining the relation of that site to the Greenwich one. Greenwich was thus incorporated on the one hand with those series which depended on the Portland Place site, while the latter was connected with those dependent (if one may use the term where all are mutually dependent) on the Greenwich site. They were all, in fact, to a certain extent linked together.

This should explain why re-observation at Greenwich, in connection with re-observation at Kew, seems likely to meet the present want best if supplemented by re-observation also at, or very near, the old Portland Place site. I have made the requisite observations (subject to some doubt) at Kew, *i.e.* at the Richmond Observatory, and at Greenwich Observatory, and I am now doing the same in the cellar above referred to, as representing Portland Place. Its exact situation is immediately in rear of All Souls' Church, Langham Place.

The Kew (or Richmond) Observatory is not a very convenient place for observations of this nature. They require attendance at all hours, whereas the observatory is situated so far from the inhabited part of Richmond as to permit of such attendance only at great personal inconvenience.[1] Also, though a precise knowledge of time is of the first importance, the absence of telegraphic communication with Greenwich Observatory and the distance from the nearest telegraph station combine at Kew to make one dependent on local transits. This is of itself a very serious objection. If to this we add that the pendulum-room at the Kew Observatory is too small to allow of the introduction of any portable stand or framework such as must of necessity be used on voyages—the very restricted space being permanently occupied by a fixed support, which does not admit of the same dispositions as would be made elsewhere for convenient observations, it remains a serious question whether Kew ought to continue to be regarded as the fundamental English pendulum station. There can be very little doubt, having regard to the paramount importance of *time* in pendulum experiments, that the fundamental station should have a perfect command of that element, such as can rarely be obtained except at a fixed astronomical observatory.

At the Langham Cellar, after due consideration, I have concluded to rely on Greenwich alone for time; sending a chronometer for the purpose every day. So far, the plan seems to be quite satisfactory, being more reliable than noting a transmitted signal at the nearest post-office.

Although I do not think I have touched on any point in this letter which is not closely connected with its primary object, I must nevertheless apologise for its length. In conclusion I have now only to repeat the offer with which I commenced it, that any one interested in, or desirous of becoming practically acquainted with pendulum swinging of this particular kind, may, at any time within the next fortnight, visit and inspect the apparatus in action, by communicating with me, at the address here given. J. HERSCHEL

1, Langham Street, Portland Place, W., December 28

[1] I estimate that I walked fully 200 miles to and from my work, in all weathers and at all hours, while carrying on the observations at Kew in September and October last.

Dante and the Southern Cross

> ". . . vidi quattro stelle
> Non viste mai, fuor ch'alla prima gente."
> *Purg.* i. 23.

No one will accuse me of excessive patriotism when I say that Dante was one of the very few chosen spirits of the fourteenth century who were thoroughly acquainted with all natural phenomena, so far as they were then known and understood, whilst he was perhaps the only one who manifested a decided contempt for all the pretensions of astrologists and necromancers (Inf. xx.). The words of such a man are deserving of the best consideration, alike of literary and scientific men; it is therefore to be hoped that before the discussion ends those best qualified to speak will throw more light on the lines in question.

As yet in answer to the query which appeared in NATURE (vol. xxv. p. 152), we have only had a quotation of a well-known passage from Humboldt's "Cosmos," and the suggestion that Dante must have derived his knowledge of the Southern Cross—evidently indicated in the lines at the head of this note—from Arabian Globes—a suggestion which, by the way, is expressed, or clearly implied, in the "Cosmos," within a page from the passage quoted. As to the remark with which both Mr. Walker and Mr. Wilks end their notes (NATURE, vol. xxv. p. 173) that "prima gente" does not refer to Adam and Eve, but to the early races which inhabited Europe and Asia, though not new, it is obviously correct to the mind of those who know how great was the cosmographic knowledge of Dante. Yet, as Count de St. Robert states in an ably-written pamphlet on the point in question (Torino, 1866), strange to say, Humboldt (who has so unhesitatingly stated the opinion of Dr. Galle that in 52° 30′ north latitude in consequence of the precession of the equinoxes, the Southern Cross might have previously reached more than 10°, and that it began to become invisible in that latitude 2900 years before Christ), believed that "prima gente" referred to our first parents.

Now, whilst admitting as possible that Dante obtained his knowledge of the stars which form the Southern Cross from the catalogue of Ptolemy (Almagest, Book vii.), on reading the passage, in which occur the two lines quoted above, especially in the original, one is irresistibly brought to think that Dante's enthusiastic description of the "quattro stelle" was inspired by the vivid description of a Christian witness of the glorious spectacle. The person most likely to have imparted such knowledge to the great poet was Marco Polo. That celebrated Venetian traveller returned from his last voyage in 1295, and lived in his native town till 1324 (Col. Yule, "The Book of Ser Marco Polo"). Dante did not visit Venice till 1320, after he had finished his "Divina Commedia," but there are many reasons for the belief that the two great men met or corresponded together.

With regard to the lines:—

> ". . . quelle tre facelle,
> Di che 'l polo di qua tutto quanto arde."
> *Purg.* viii. 89.

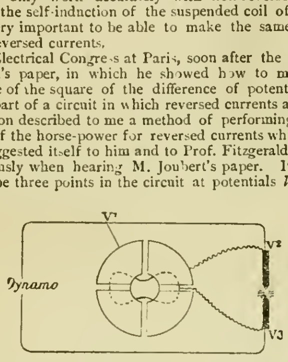
which Dante says were high when the "quattro stelle" were low, it is difficult to agree with any of the commentators, because neither the Magellanic clouds, nor Achernar, nor any three prominent southern stars, correspond satisfactorily to the "tre facelle" alluded to. It must not be forgotten that accurate

astronomical and geographical knowledge is but of recent date, and, as already stated, Dante formed many of his cosmographic conceptions chiefly from hearsay. N. PERINI

The Horse-Power given to any Part of a Circuit by Intermittent Light

SOME time ago, with Prof. Ayrton, I designed and constructed an instrument to measure the horse-power given electrically to any incandescent or arc lamp, or to any part of a circuit, an improvement on the instrument previously devised by M. Deprez; the pointer of a suspended coil moves at once to a mark on a scale which tells the horse-power. The instrument is dead beat, and, what is very important, by a special commutator arrangement it can be calibrated with much smaller forces than it is intended to measure. The current in the suspended coil is proportional to the difference of potential at the ends of a part of the circuit, and the fixed current which causes its deflection is the total main current in the circuit, so that the deflection represents the product of these two factors. The instrument was described at the Society of Arts in March last, and was exhibited at the British Association meeting at York. It will, however, necessarily only work accurately with non-reversed currents because of the self-induction of the suspended coil of fine wire, and it is very important to be able to make the same measurement for reversed currents.

At the Electrical Congress at Paris, soon after the reading of M. Joubert's paper, in which he showed how to measure the mean value of the square of the difference of potential at two ends of a part of a circuit in which reversed currents are flowing, Prof. Ayrton described to me a method of performing the measurement of the horse-power for reversed currents which seemed to have suggested itself to him and to Prof. Fitzgerald of Dublin simultaneously when hearing M. Joubert's paper. It was this: Let there be three points in the circuit at potentials V_1, V_2, V_3,



at any instant, and let there be a known resistance R (with no self-induction) between V_1 and V_2. Let V_3 be connected with the needle of a Thomson's electrometer, and let V_1 and V_2 be connected with the quadrants, V_1 being also connected with the outside of the Leyden jar: then the deflection of the needle measures the mean value of

$$(V_2 - V_1)\left(V_3 - \frac{V_2 + V_1}{2}\right).$$

Now let the needle and a pair of quadrants be connected with V_2, the other pair with V_1, and we measure the mean value of the square of $(V_2 - V_1)$. The difference of these measurements is easily seen to be R times the expended energy which we want to know.

I was not present when Professors Ayrton and Fitzgerald communicated their idea to one another, but immediately afterwards Prof. Ayrton explained it to Sir William Thomson and to me together, making sketches of the necessary connections. Sir William thought well of it, but feared that perhaps the present quadrant electrometer would not be sensitive enough for the measurements. We suggested, however, the use of our multireflex arrangement (see *La Lumière Electrique*, October 5, 1881) for creating greater sensitiveness, and as he was pleased with the idea, we have, since that time, in our very short intervals of leisure, been trying to arrange an electrometer which shall be sensitive enough for the purpose.

I observed to-day that M. Potier in the October number of the *Journal de Physique* publishes the same idea, and I wish to place it on record that the fundamental idea of the new process, which seems to me very feasible and of considerable practical importance, occurred to Messrs. Ayrton, Fitzgerald, and Potier independently. JOHN PERRY

Talgarth Road, West Kensington, December 6

The New Red Star in Cygnus

THE above star, which I found on the 22nd of May last, and which then appeared of the 9th magnitude, and reached 8 m. on June 8, seems now no more than 12 m. Estimations of very small magnitudes are, of course, very difficult, but I believe I am not under the mark in saying 12 m., as I found the star not easy with a 4½ inch O.G. At the same time its deep crimson seemed very striking by glimpses, and in its present state it is, perhaps, the smallest among the stars whose red colour has been observed. It will probably have to be classed among the most remarkable variables. J. BIRMINGHAM

Meteor

TAKING a look at the eclipse of the moon on December 5, about 5.44 p.m., I happened to see a meteor that is, I think, very noteworthy, though, perhaps from distance, its apparent size was so small that I might have scarcely seen it but for the temporary lessening of the light of the moon. Its motion was, throughout its visible course, horizontal and slow. When it met my eyes, it was just below the Pleiades. I followed its flight to the northern end of the eastern sky; there it seemed to go on out of my sight, without fall or collapse: for aught I know, I might have observed it even from the extreme south, had my eyes been turned thither at the outset; I would draw attention to this fact, as well as to its horizontal motion and its seemingly slow progress. The grandeur of the glories displayed by that night's clear sky was at its height as this mysterious stranger passed above our winsome satellite—then a thing of "eerie beauty," its glistening golden ring half-clasping, like "the old moon in the new moon's arms," the earth-shadowed orb over it, and the latter shimmering with the maroon ember-like sheen called by the French *la lumière cendrée*.

Combe Vicarage, near Woodstock, December 16

SEA-SICKNESS.—This must be declined as a subject for correspondence.

A NEW ELECTRICAL STORAGE BATTERY[1]

THE great utility of some thoroughly practical method of conserving electric force has caused a great deal of attention to be applied to the subject; no system of electric supply can be considered as perfect until some means is used to so store the force generated that it may be drawn off equally and regularly, and this whether the generator be on or off. If we take, as an example of electric supply, the present systems of electric lighting, it is at once seen, should an accident or stoppage take place in the machinery generating the current, the whole of the apparatus such as lamps or motor-machines are influenced; should there be a reservoir of electricity between the generator and the apparatus of whatever sort for utilising the force this inconvenience would not occur.

All the present systems of storing electricity depend on certain chemical changes produced by electrolysis.

I have gone through a long series of experiments on storing electricity and made many forms of cells, one being a porous pot containing dilute hydric sulphate and a sheet of lead, in an outer vessel containing a sheet of lead in solution of acetate of lead, the plate in the porous pot being made the positive electrode; this cell had the power of storing electricity, by peroxidising the positive electrode, and depositing from the acetate of lead solution metallic lead on the negative electrode, the hydrogen having combined to form acetic acid. On discharging the peroxide is reduced, and the oxide formed during discharge on the other plate dissolves in the acetic acid, forming the original solution of acetate of lead; by this means I eliminated the injurious effects of the hydrogen on charging.

During my experiments I found that red oxide of lead is a very bad conductor of electricity, and the peroxide a good conductor. I also discovered that by amalgamating lead plates with mercury a marked increase was

[1] "On a New Electrical Storage Battery." By Henry Sutton (Ballarat Victoria). Communicated to the Royal Society by the President.

immediately manifest in polarisation effects, the plates becoming more uniformly and rapidly peroxidised when used as positive electrodes, and local action entirely disappearing. These mercury amalgamated plates at once give me an advance of other cells. I used them in many ways, constructing cells in which the positive plate was amalgamated, and the negative coated with red oxide, or with peroxide, produced by treating red oxide with dilute hydric nitrate till the brown precipitate of peroxide fell, the precipitate being washed and painted on the electrode. I also amalgamated the negative electrode simply. I found that in every way positive electrodes amalgamated produced the best results. I also made cells in which either peroxide or red oxide was formed into a porous conglomerate, using the conglomerates as electrodes, immersed in dilute hydric sulphate. I constructed cells with parallel plates, red oxide or peroxide being filled in between the plates; in this experiment red oxide is useless and peroxide efficient. In all these experiments I succeeded in storing electricity to different extents.

Having thoroughly satisfied myself that positive electrodes amalgamated with mercury were the best, I investigated the behaviour of various forms of negative electrode, having in view the conservation of the hydrogen; this I thought to do by occluding the hydrogen in suitable electrodes, as spongy platinum or metallic palladium; but as both these methods would be useless owing to expense I did not even experiment on them.

I further thought of having negative electrodes, whose oxides should be soluble in the solution, and which could be redeposited from the solution, or of having metallic solutions from which metal could be deposited, the resulting solution being such that should, on the oxidation of the deposited metal, combine with the oxide and again form the original solution.

I thought that success in this manner would result in a powerful and constant source of stored energy, the cell would not polarise itself during discharge, as is the case in both Planté and Faure cells; in these cells the peroxide formed by the discharge produces a contrary electromotive force.

Experimenting from this train of thought, the results I have obtained are such as to have an important practical bearing on the future of electric work.

The experiments comprised amalgamated lead as a positive electrode with negative electrodes composed of either zinc, iron, or copper, in each case the solution between the electrodes being a salt of the metal composing the negative electrode. With zinc, sulphate of zinc was the solution; with iron, sulphate of iron; and with copper, sulphate of copper. In all these cases the results were not only far more powerful than with any form of cell I had previously devised, but also very constant, the polarisation lasting many times longer than in any other form of cell. The cell with zinc negative electrode I discarded, owing to the necessity there would be to keep the zinc plate amalgamated to prevent local action; the iron negative electrode was set aside owing to the iron oxidising when the cell was not in use. The cell having a negative electrode of copper, a positive electrode of lead amalgamated with mercury and a solution of cupric sulphate, I have adopted as a thoroughly economical, lasting, and practical form of storage reservoir. The chemical changes in this cell are exceedingly interesting and beautiful, the cell being composed of a sheet of lead cleaned with dilute sulphuric acid and amalgamated thoroughly with mercury, and a sheet of thin copper a little shorter; the two sheets are perforated with a number of holes and then rolled in a spiral, separated by rubber bands cut every five inches, the holes in plates and cuts in rubber bands being to allow free circulation of the solution (the short plate being uppermost before rolling). This combination is immersed in a solution of cupric sulphate, and the amalgamated lead plate made the positive electrode of a suitable source of electricity, the chemical action being that the oxygen of the decomposed solution combines with the lead, forming a perfectly even coating of the insoluble peroxide, the hydrogen replacing the copper of the solution, and the copper being deposited in the metallic state on the negative electrode. As the decomposition of the cupric sulphate proceeds the solution gradually loses its azure blue colour, becoming more acid, and finally when the whole of the copper is deposited, we have the solution colourless and transformed into hydric sulphate and water, the positive electrode peroxidised and copper deposited on the negative electrode. During discharge the peroxide is reduced and the copper element oxidised, the oxide combining with the acid and forming cupric sulphate, the solution returning to its original colour. This change of colour forms a beautiful means of telling when the cell is charged; it is a veritable charging gauge. The power of this cell is very great and very constant; it can be made to last for hours, the time being dependent on the quantity of cupric sulphate decomposed.

I have, by the decomposition and recomposition of one pint of cupric sulphate, obtained over two hours' effective work in heating to a red heat one inch of No. 28 iron wire, the cell measuring internally 4 inches deep and 4 inches diameter.

I constructed cells with free crystals of cupric sulphate suspended in the solution, and found that the presence of free crystals prevented the oxidation of the amalgamated lead electrode, it being essential that the solution become slightly acid before the peroxide will form. The cell during charging gives out a peculiar rattling noise, which I consider due to the deposition of copper on the negative electrode altering the form of the spiral.

A practical form of cell for storing purposes ought to be made, by fixing a series of amalgamated lead plates in a box in grooves, as in Cruikshank's trough battery, filling the interval between the plates with solution of cupric sulphate, and passing a current through of sufficient tension to overcome the contrary electromotive force of the series, the positive sides of the plates being peroxidised and copper deposited on the negative sides. I have two boxes on this plan, each containing twenty-five plates, the total being equivalent to fifty cells. By this means batteries of great tension can be charged from thirty Bunsens. A number of twenty-five plate boxes can be coup ed for quantity of charging, and for tension during discharge. Twenty such boxes, one foot square, internal measurement, will give in series a battery of 500 pairs of one foot square plates.

It will be seen from the foregoing that this method of conserving energy has a wide field before it, and as it will benefit fellow-workers in science, placing in their hands a means of experimenting with powerful electric currents, I give it without reservation, freely and untrammelled by patent rights, for their use.

THE BISCHOFFSHEIM OBSERVATORY

THIS observatory built at the expense of M. R. Bischoffsheim, the member of the French Lower House for Nice, is situated on Mont Gros, at an altitude of about 370 metres, and at a distance of eight English miles on the old Route de la Corniche, so well known and appreciated by the tourists travelling by road from Nice to Genoa. M. Celora, Milan astronomer, Commander Bahet of the French Staff, and M. Perrotin, the present director of the Bischoffsheim Observatory, have ascertained electrically and astronomically, the longitude and latitude of the new establishment which has been connected with Paris and Milan, by unquestionable observations.

The buildings have been constructed under the direct supervision of M. Garnier, the architect of the Paris

Opera, and distributed skilfully in several favourable sites of a large park having a surface of 80 acres.

The smaller meridian circle by Gauthier is in its place, and can be used for daily determinations. The large meridian circle by Brünner will be finished in the first month of 1882. The object glass has 8 inches diameter, and has been focussed to a distance of 10 feet. The smaller equatorial with an object-glass of 14 inches, and focussed to 27 feet, has been made by Eichens, and will be ready for observations at the same time as the larger meridian circle. The larger equatorial will have an object-glass of 28 inches, and will be focussed to 52 feet. The glasses have been made by Feil; Henry Brothers are polishing them. The instrument will be constructed by Eichens and Gauthier The work is proceeding favourably, but it is impossible to state when it will be completed.

M. Lœwy, sub-director of the Paris Observatory, has designed an apparatus for preventing the perturbations produced by the flexion of the axis when observations are taken at a large angular distance from the zenith. The building will have a diameter of sixty-four feet, with a rotating roof of copper, worked by hand-machinery, as designed by Gardiner.

The Bischoffsheim observatory will not be confined to astronomical observations. The donor having been taught by Leverrier in astronomy has felt it a duty to extend his donation to magnetical and meteorological observations, too often neglected in French observatories. A magnetical pavilion has been built with extensive cellars, for continuous self-registering apparatus. The registration takes place by photography as in Kew, and is made with instruments by Adie, the maker of the Kew set of registers. As in Kew, a "rez-de-chaussée" has been built for direct force and direction observations. The instruments have been made by Brunner.

The installation of the meteorological instruments has been made under the direct supervision of M. Mascart, the director of the French Meteorological Office. A constant staff has been selected by M. Bischoffsheim, and is now on duty. The direction has been given to M. Perrotin, formerly assistant astronomer to M. Tisserand when he was director of Toulouse Observatory. The assistant astronomer is M. Carvallo, formerly a pupil in the Polytechnic School, and who has taken his astronomical honours in the special school established by Rear-Admiral Mouchez at the Paris Observatory. M. Puiseux, formerly pupil of the Polytechnic School, will have the control of magnetical and meteorological observations.

Two houses have been built—one for the administration and the other for the direction. The first floor of this staircase has been fitted up entirely for boarding foreign astronomers who are desirous of making observations in this magnificent astronomical "caravanserai." M. and Mdme. Struve and M. Tachini have promised already to spend some time there next winter.

It should be noted that it was probably in a tour made in England with Leverrier, when the great astronomer was made an honorary doctor of Cambridge University, that M. Bischoffsheim meditated on the opportunity of establishing an observatory entirely of his own. Up to that time he had spent his time in the observation of stars which shine in a less elevated sphere than the heavenly skies. But Leverrier's conversation and intimacy led him to appreciate other unfading beauties.

The Bureau des Longitudes has agreed to take possession of the observatory, which will be handed over to it with a sufficient endowment to keep it decently. It is estimated that the money spent in purchasing the estate, &c., will exceed 120,000*l.*, and that the endowment will be more than 2000*l.* a year. This handsome donation must be noted as being a revolution in French generosity towards science. Up to this time our neighbours confined themselves to bequeathing legacies and lavishing posthumous generosities.

FOSSIL FLORA OF SUMATRA[1]

THIS is a paper of some twenty pages and six plates. Herr Verbeek sent in 1874 a small collection of fossil plants from Sumatra to Switzerland, which were described by Heer, and in the following year the second collection, now described, was received, no others having been found in the interval. The plates contain twenty-two figures, most of them representing fragments of simple ovate leaves, supposed, with two exceptions, to be allied to existing species of the Indian mainland or archipelago. The mollusca in the overlying strata point to an Eocene age. The exceptions are a Eucalyptus and a small leaflet ascribed to Cassia, and now represented, it is here supposed, by *C. lævigata* of tropical America, but the determination rests on slender grounds. The majority of them, in fact, though doubtless the best that could be made from such material, must necessarily be almost mere guesses. The value of such guesses may be inferred from a similar work by the same author on the fossil flora of Madeira.

In this case several of the commonest indigenous plants of Madeira were referred to extra-Madeiran plants. For instance, the terminal leaflets of *Rubus discolor* were referred to *Corylus australis*, and various leaflets of *Rubus grandiflora* are figured as *Corylus australis*, *Ulmus suberosa*, and *Psoraleadentata;* the so-called *Pistacea Phæacum* is the common myrtle, the *Ilex Hartingi* is the Madeira *Vaccinium*, and the figures of *Myrica Faya* belong to *Ardisia excelsa*. In this case the mistakes are the more singular, as Prof. Heer had actually sojourned in Madeira, and the plants are the commonest on the island. If with even exceptionally favourable circumstances such mistakes can be made, generalisers should surely be cautious in building theories upon the ages of formations, &c., when they have been determined upon the evidence of fossil plants. It is unfortunate that on evidence as trivial, and even more questionable, we read in Lyell of the MIOCENE outbursts of Mull, of Iceland, and Greenland, of the MIOCENE deposits of Bovey Tracy, &c.

It is important, however, that fossil plants should be figured and described, for if the generic and specific names, except when based on ample material, are regarded merely as an individual opinion, the determinations become of use. Whatever is unsatisfactory in the work is inherent to the subject, for few possess the zeal and untiring industry of Heer. If he would only make clear to his readers the reasons which enable him in his own mind to determine the genus to which an ordinary type of leaf, with neither top nor base, belongs, and would be less positive where nothing positive is possible, his works would acquire a scientific value which some justly think they hardly at present possess.

J. S. G.

THE VOYAGE OF THE "VEGA"[2]

II.

BARON NORDENSKJÖLD frequently refers to what Mr. Leslie renders "self-dead" animals, meaning animals that have died a natural death, in distinction to those that have been killed by hunters or by other animals. The rarity of such "self-dead" animals is remarkable, especially along the north coast of Asia, where there are few hunters and fishers, and where immense numbers of animals must die. While sailing along the Taimur coast, large numbers of dead fish (*Gadus polaris*) were seen lying on a block of ice, and strewed along the bottom of the sea, which Baron Nordenskiöld notices as being very unusual.

[1] By Dr. Oswald Heer (*Neue Denkschriften der schweizerischen Gesellschaft*, vol. xxviii. Zürich, 1881)

[2] "The Voyage of the *Vega* round Asia and Europe; with a Historical Review of previous Journeys along the North Coast of the Old World." By A. E. Nordenskjöld. Translated by Alexander Leslie. Five steel portraits, numerous maps and illustrations. Two vols. (London: Macmillan and Co., 1881.) Continued from p. 183.

"They had probably perished from the same cause, which often kills fish in the river Ob in so great numbers that the water is infected, namely, from a large shoal of fish having been inclosed by ice in a small hole, where the water, when its surface has frozen, could no longer by absorption from the air replace the oxygen consumed, and where the fish have thus been literally drowned. I mention this inconsiderable *find* of some self-dead fish, because self-dead vertebrate animals, even fish, are found exceedingly seldom. Such *finds* therefore deserve to be noted with much greater care than, for instance, the occurrence of animal species in the neighbourhood of places where they have been seen a thousand times before. During my nine expeditions in the Arctic regions, where animal life during summer is so exceedingly abundant, the case just mentioned has been one of the few in which I have found remains of recent vertebrate animals which could be proved to have died a natural death. Near hunting-grounds there are to be seen often enough the remains of reindeer, seals, foxes, or birds that have died from gunshot wounds, but no self-dead Polar bear, seal, walrus, white whale, fox, goose, auk, lemming or other vertebrate. The Polar bear and the reindeer are found there in hundreds, the seal, walrus, and white whale in thousands, and birds in millions.[1] These animals must die a "natural" death in untold numbers. What becomes of their bodies? Of this we have for the present no idea, and yet we have here a problem of immense importance for the answering of a large number of questions concerning the formation of fossiliferous strata. It is strange in any case that on Spitzbergen it is easier to find vertebræ of a gigantic lizard of the Trias, than bones of a self-dead seal, walrus, or bird, and the same also holds good of more southerly inhabited lands."

Another problem of great importance is suggested by the finding of some yellow specks on the snow of the Taimur coast, which turned out to be carbonate of lime of an unusual form of crystallisation, and which the Baron believes were probably of interplanetary origin. He gives a brief sketch of his previous observations in the high north on this subject, referring also to what has been done by M. Tissandier, and during the last English polar expedition, and to the special suitability of the uninhabited Arctic regions for the collection of what is believed to be cosmic dust. It is certainly a subject which deserves the attention of future expeditions, and especially of the polar observing stations which are in a fair way of being established.

"It may appear to many that it is below the dignity of science to concern one's self with so trifling an affair as the fall of a small quantity of dust. But this is by no means the case. For I estimate the quantity of the dust that was found on the ice north of Spitzbergen at from 0·1 to 1 milligram per square metre, and probably the whole fall of dust for the year far exceeded the latter figure. But a milligram on every square metre of the surface of the earth amounts for the whole globe to five hundred million kilograms (say half a million tons)! Such a mass collected year by year during the geological ages, of a duration probably incomprehensible by us, forms too important a factor to be neglected, when the fundamental facts of the geological history of our planet are enumerated. A continuation of these investigations will perhaps show, that our globe has increased gradually from a small beginning to the dimensions it now possesses; that a considerable quantity of the constituents of our sedimentary strata, especially of those that have been deposited in the open sea far from land, are of cosmic origin; and will throw an unexpected light on the origin of the fire-hearths of the volcanoes, and afford a simple explanation of the remarkable resemblance which unmistakably exists between plutonic rocks and meteoric stones."[1]

[1] I can remember only one other instance of finding self-dead vertebrate animals, viz. when in 1873, as has already been stated (p. 110), I found a arge number of dead rotges on the ice at the mouth of Hinloopen Strait.

After leaving Cape Chelyuskin, the *Vega* sailed for a considerable distance over what, in existing maps, is set down as land; and although there was necessarily little time for accurate surveying, still it will be found that the expedition has done much to render accurate the geography of the north coast of Asia. After sailing down the east side of the Taimur Peninsula, close by the land, the vessel was directed almost straight eastwards towards the most southerly of the New Siberian Islands, still keeping as near the coast of the mainland as practicable. Off the delta of the Lena, which within the last week has come so prominently before us in connection with the *Jeannette* expedition, the *Vega* parted with the *Lena*, which entered the river, to establish regular traffic by steamer. It was only after leaving Cape Chelyuskin that ice in any quantity was met with so as to hamper the progress of the vessels, and Baron Nordenskjöld states that had the coast-water been better known so that he could have kept closer to land, the latter part of the voyage would have been as free from obstruction as the former.

Here follows an interesting chapter on the commercial navigation of the great Siberian rivers, and on the geography and economical condition of Siberia. It contains indeed a summary of all that is known to science of the immense country, with much that is the result of Baron Nordenskjöld's own research or observations, and with speculations on geology that are not likely to be let pass unchallenged. The *Lena* had some difficulty in navigating the delta of the river, for the old maps of 140 years ago were useless, the changes at the mouth of the river in that time has been so great. The Baron draws an interesting parallel between Siberia and America north of the 40th parallel.

He then gives a sketch of his own journey up the Yennissi in 1875, in connection with which we give a view on that river (Fig. 7).

"As is the case with all the other Siberian rivers running from south to north,' the western strand of the Yenisej, wherever it is formed of loose, earthy layers, is also quite low and often marshy, while on the other hand the eastern strand consists of a steep bank, ten or twenty metres high, which north of the limit of trees is distributed in a very remarkable way into pyramidal pointed mounds. Numerous shells of crustacea found here, belonging to species which still live in the Polar Sea, show that at least the upper earthy layer of the *tundra* was deposited in a sea resembling that which now washes the north coast of Siberia.

"The *tundra* itself is in summer completely free of snow, but at a limited depth from the surface the ground is continually frozen. At some places the earthy strata alternate with strata of pure, clear ice. It is in these frozen strata that complete carcases of elephants and rhinoceroses have been found, which have been protected from putrefaction for hundreds of thousands of years. Such *finds*, however, are uncommon, but on the other hand single bones from this primeval animal world occur in rich abundance, and along with them masses of old drift-wood, originating from the Mammoth period, known by the Russian natives of Siberia under the distinctive name of 'Noah's wood.' Besides there are to be seen in the most recent layer of the Yenesej *tundra*, considerably north of the present limit of actual trees, large tree-stems with their roots fast in the soil, which show that the limit of trees in the Yenesej region, even during our geological period, went further north than now, perhaps as far as, in consequence of favourable local circumstances, it now goes on the Lena.

"On the slopes of the steep *tundra* bank and in several

[1] Namely, by showing that the principal material of the plutonic and volcanic rocks is of cosmic origin, and that the phenomena of heat, which occur in these layers, depend on chemical changes to which the cosmic sediment, after being covered by thick terrestrial formations, is subjected.

of the *tundra* valleys there is an exceedingly rich vegetation, which already, only 100 kilometres south of Yefremo-Kamen, forms actual thickets of flowering plants, while the *tundra* itself is overgrown with an exceedingly scanty carpet, consisting more of mosses than of grasses. Salices of little height go as far north as Port Dickson (73° 30′ N.L.), the dwarf birch (*Betula nana*, L.) is met with, though only as a bush creeping along the ground, at Cape Schaitanskoj (72° 8′ N.L.); and here in 1875, on the ice-mixed soil of the *tundra*, we gathered ripe cloudberries. Very luxuriant alders (*Alnaster fruticosus*, LEDEB.) occur already at Mesenkin (71° 28′ N.L.), and the Briochov Islands (70° to 71° N.L.) are in several places covered with rich and luxuriant thickets of bushes. But the limit of trees proper is considered to begin first at the great bend which the river makes in 69° 40′ N.L., a little north of Dudino. Here the hills are covered with a sort of wood consisting of half-withered, grey, moss-grown

FIG. 7.—River view on the Yennissi.

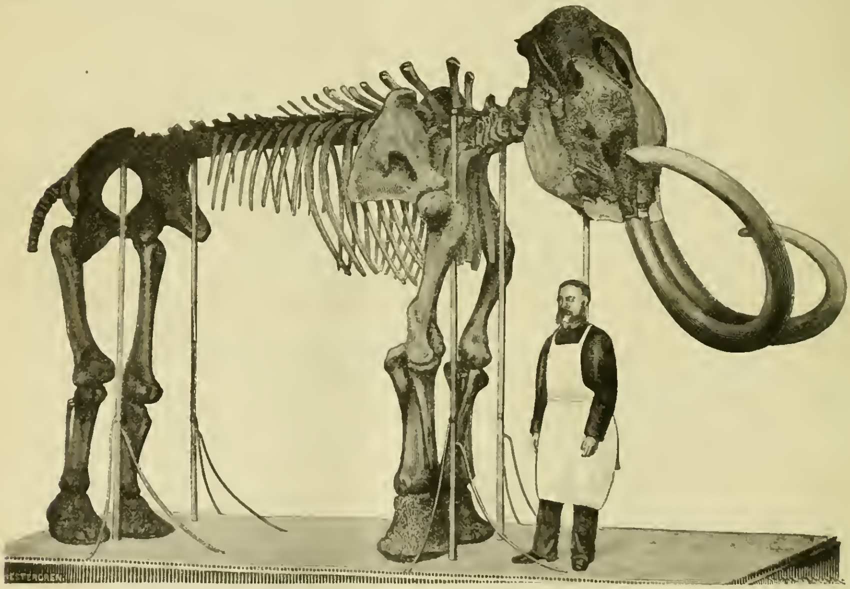

FIG. 8.—Mammoth Skeleton in the Imperial Museum of the Academy of Sciences in St. Petersburg.

larches (*Larix sibirica*), which seldom reach a height of more than seven to ten metres, and which much less deserve the name of trees than the luxuriant alder bushes which grow nearly 2° farther north. But some few miles south of this place, and still far north of the Arctic Circle, the pine forest becomes tall. Here begins a veritable forest, the greatest the earth has to show, extending with little interruption from the Ural to the neighbourhood of the Sea of Ochotsk, and from the fifty-eighth or fifty-ninth degree of latitude to far north of the Arctic Circle, that is to say, about one thousand kilometres from north to south, and perhaps four times as much from east to west. It is a primeval forest of enormous extent, nearly untouched by the axe of the cultivator, but at many places devastated by extensive forest fires.

"On the high eastern bank of the Yenisej the forest begins immediately at the river bank. It consists principally of pines: the cembra pine (*Pinus Cembra*, L.), valued for its seeds, enormous larches, the nearly awl-formed Siberian pine (*Pinus sibirica*, Ledeb.), the fir (*Pinus obovata*, Turcz.), and scattered trees of the common pine (*Pinus sylvestris*, L.). Most of these already north of the Arctic Circle reach a colossal size, but in such a case are often here, far from all forestry, grey and half-dried up with age. Between the trees the ground is so covered with fallen branches and stems, only some of which are fresh, the others converted into a mass of wood-mould held together only by the bark, that there one willingly avoids going forward on an unbroken path. If that must be done, the progress made is small, and there is constant danger of breaking one's bones in the labyrinth of stems. Nearly everywhere the fallen stems are covered, often concealed, by an exceedingly luxuriant bed of mosses, while on the other hand tree-lichens, probably in consequence of the dry inland climate of Siberia, occur sparingly. The pines, therefore, want the shaggy covering common in Sweden, and the bark of the birches which are seen here and there among the pines is distinguished by an uncommon blinding whiteness."

FIG. 9.—Nutti and his wife Aitanga.

After parting with the *Lena* the *Vega* made for the New Siberian Islands, of great interest to science on account of the abundant remains of the extinct mammoth found thereon. "We know by the careful researches of the Academicians Pallas, von Baer, Brandt, von Middendorf, Fr. Schmidt, &c., that the mammoth was a peculiar northern species of elephant with a covering of hair, which, at least during certain seasons of the year, lived under natural conditions closely resembling those which now prevail in middle and even in northern Siberia. The widely extended grassy plains and forests of North Asia were the proper homeland of this animal, and there it must at one time have wandered about in large herds." The mammoth remains the Baron shows are derived from a gigantic animal form, living in former times in nearly all the lands now civilized, and whose carcase is not yet everywhere completely decomposed. Hence the great and intense interest which attaches to all that concerns this wonderful animal (Fig. 8).

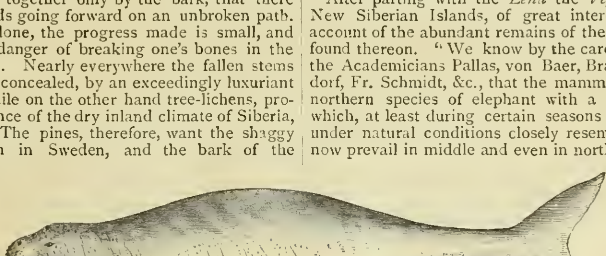

FIG. 10.—Reconstructed form of the sea-cow.

Baron Nordenskiöld then gives an interesting account of all the leading mammoth finds from the earliest period down to the present day. Portions of skeletons of other animal forms have been found in considerable numbers in the New Siberian Islands, and also certain remarkable "wood-hills," highly enigmatical as to their mode of formation.

"These hills are sixty-four metres high, and consist of thick horizontal sandstone beds alternating with strata of fissile bituminous tree stems, heaped on each other to the top of the hill. In the lower part of the hill the tree stems lie horizontally, but in the upper strata they stand upright, though perhaps not rootfast.[1] The flora and fauna of the island group besides are still completely unknown, and the fossils, among them ammonites with exquisite pearly lustre,

[1] Hedenström, *loc. cit.* p. 128. To find stranded driftwood in an upright position is nothing uncommon.

which Hedenström brought home from the rock strata on Kotelnoj Island, hold out inducement to further researches, which ought to yield the geologist valuable information as to the former climate and the former distribution of land and sea on the surface of the globe."

In connection with the state of the ice and the sea here, and the absence of glaciers on the coast, Baron Nordenskiöld gives a classified account of what he deems the various forms of ice. We can only here give a list of the various forms, referring the reader to the book itself for details. We have (1) icebergs, (2) glacier ice-blocks, (3) pieces of ice from the ice-foot; (4) river-ice; (5) bog-ice; (6) sea-ice or heavy ice. After passing Cape Chelgaskoi, on the east of Chaun Bay, on September 6, progress became much slower, and they had become heartily tired of "new ice, shallow water, and fog, and fog, shallow water, and new ice." Here for the first time since leaving Yugor Schar, signs of humanity were seen in the shape of some Chukchi natives who came out to the ship in their boats. A detention of six days at Cape Irkaipi (180° east longitude) afforded an opportunity for examining the games of the race known as Onkilon, who formerly inhabited these regions, and some centuries ago were driven by the Chukchis, according to tradition, to some remote islands in the polar sea. Kolyuchin Bay, just at the north entrance to Behring Strait, was reached on September 28, and just beyond it, and a mile from the shore, the *Vega* was caught in the ice and detained for ten months, till July 18, 1880. It was only after the lapse of some time that the expedition realised that they were caught at last, and serious preparations made for spending the winter. Meteorological and astronomical observatories were erected on shore, and a well-arranged method adopted for carrying out observations of various kinds. To some of the specially scientific results we shall probably refer in separate articles, and particularly to the interesting auroral observations both here and during other expeditions under the guidance of Baron Nordenskjöld. Some accurate notes as to ice-measurements are given in the neighbourhood of the *Vega's* winter quarters, which we give here, as statements on the subject are sometimes so vague.

"When it had become evident that we could make no further advance before next year, Lieut. Brusewitz occasionally measured the thickness of the newly formed ice, with the following results:

THICKNESS OF THE ICE.

1 Dec.	56 centimetres.	1 May,	154 centimetres.
1 Jan.	92 "	15 "	162 "
1 Feb.	108 "	1 June,	154 "
15 "	120 "	15 "	151 "
1 Mar.	123 "	1 July,	104 "
1 April	128 "	15 "	67 " (full of holes).
15 "	139 "	18 "	The ice broke up."

"The exact position of the *Vega* was 67° 4′ 49″ north latitude, and 173° 23′ 2″ west longitude. The dietary and hygienic arrangements were such that no trace of scurvy occurred during the whole winter, and no illness to speak of.

"The greatest cold which was observed during the different months was in

Oct. the 24th—20°·8	March the 29th—39°·8
Nov. the 30th—27°·2	April the 15th—38°·0
Dec. the 23rd—37°·1	May the 3rd—26°·8
Jan. the 25th—45°·7	June the 3rd—14°·3
Feb. the 2nd—43°·8	July the 2nd—1°·0

"Twice we had the barometer uncommonly high, viz.:

On the 22nd December 6 A.M. 782·0 (0°) mm.
On the 17th February 6 A.M. 788·1 (0°) mm.

"The lowest atmospheric pressure, 728·8 (0°) mm., occurred on the 31st December at two o'clock P.M."

The ship was beset in the neighbourhood of a number of Chukchi encampments, and with the natives the most friendly intercourse was kept up during the whole year. Chukchi trading parties from a distance passing on to trade in one of the islands in the strait, made the *Vega* a regular place of call, and thus a great amount of information was gathered from these people of much ethnological value. They have evidently no connection with the Eskimo, whose origin must be sought within the American continent itself. The Chukchis would seem to have been driven up to their present inhospitable abodes a few centuries ago, by commotions in Central Asia; and when the Russians first came into contact with them they were found to be a brave and warlike race whom it was very difficult to subdue. At present they are quiet, harmless, good-natured, and dirty, some having flocks of reindeer and living inland, while the coast Chukchis live largely by fishing. Lieutenant Nordquist learned the language of the people, and was thus able to have important intercourse with them. Large collections were made of their clothing, implements, weapons, utensils, &c., as also of their drawings, for like the Eskimo they have a wonderful capacity for art of a rude and elementary but genuine kind. We give on the preceding page the portraits of a Chukchi and his wife, of such portraits the volume contains many (Fig. 9). Animal lifewas not specially abundant in the land; no bears, an occasional wolf, with a number of foxes, white, red, and black, and hares.

"On our arrival most of the birds had already left these regions, so inhospitable in winter, or were seen high up in the air in collected flocks, flying towards the south entrance of Behring's Straits. Still on the 19th October an endless procession of birds was seen drawing towards this region, but by the 3rd November it was noted, as something uncommon, that a gull settled on the refuse heaps in the neighbourhood of the vessel. It resembled the ivory gull, but had a black head. Perhaps it was the rare *Larus Sabinii*, of which a drawing has been given above. All the birds which passed us came from the north-west, that is, from the north coast of Siberia, the New Siberian Islands or Wrangel Land. Only the mountain owl, a species of raven and the ptarmigan wintered in the region, the last named being occasionally snowed up."

Additional observatories were built during the winter, so that there was a regular collection of them on shore. And so with regular work and amusement, and occasional visits to the Chukchis, the winter passed happily; and on April 23, returning spring brought with it the birds in their migration northward, beginning with the snow-bunting, the "sparrow of the north." The bird and mammal fauna of the Chukch Peninsula and north-east Siberia generally, we may say, Baron Nordenskjöld found to be markedly different from those which prevail in other parts of the Arctic Regions. On July 18, 1880 the *Vega* was as suddenly released from the ice as she was caught, and all at once found herself free to pass through Behring Straits, and thus accomplished the North-east Passage. Space prevents us from following the Expedition in their cruise round the rest of the coast of the Old World. The members of the expedition continued their observations up to the last, and even in Japan, China, Ceylon, and other places were able to add something to our existing knowledge. Considerable time was spent in visiting the north-east coast of Asia, the north-west coast of America, and the islands between. The results are much important information on the natural history and geology of those regions, and a long account of our knowledge of the north coast of Asia from the earliest time including the extensive series of Russian voyages of discovery with which the names of Behring, Steller, and others are associated. Of Steller, Baron Nordenskjöld has the highest opinion, as well as of the value of his work in natural history on Behring Island, and his death

at thirty-seven years of age, through the jealousy and tyranny of Siberian officials was a cruel loss to science. In these chapters, all that is known to science concerning North Siberia and the neighbouring islands has been carefully epitomised, and will form a valuable manual for future scientific work. In cruising from the Asiatic to the American coast, Baron Nordenskjöld makes a remark which has an important bearing on a recent correspondence in these columns. "As in all the Polar Seas," he states, "of the northern hemisphere, so also here, the eastern side of the Straits was ice-bestrewn; the western, on the other hand, clear of ice." We regret that we cannot enter in detail on the many interesting facts given by Baron Nordenskjöld on the natural history of St. Lawrence, Behring, and other islands between Asia and America. He has collected all the information attainable on Steller's sea-cow (*Rhytina Stelleri*), which on Steller's visit to Behring Island in 1741 was found pasturing in large herds on the abundant sea-weed on the shores of the island. Twenty-seven years after, not a specimen was to be found, and it was believed to be then extinct. But Baron Nordenskjöld adduces evidence to prove that a specimen was seen twenty-seven years ago, though there can be little doubt that it has really gone the way of the mammoth. The Baron does not believe that its extinction is due to the destruction by hunters, but that it was a survival from a past age doomed to extinction, which overtook it when driven from its pastures on the shores of Behring Island.

"*Steller's sea-cow* (*Rhytina Stelleri*, Cuvier) in a way took the place of the cloven-footed animals among the marine mammalia. The sea-cow was of a dark-brown colour, sometimes varied with white spots or streaks. The thick leathery skin was covered with hair which grew together so as to form an exterior skin, which was full of vermin and resembled the bark of an old oak. The full grown animal was from twenty-eight to thirty-five English feet in length and weighed about sixty-seven cwt. The head was small in proportion to the large thick body, the neck short, the body diminishing rapidly behind. The short fore-leg terminated abruptly without fingers or nails, but was overgrown with a number of short thickly placed brush-hairs; the hind-leg was replaced by a tail-fin resembling a whale's. The animal wanted teeth, but was instead provided with two masticating plates, one in the gum the other in the under jaw. The udders of the female, which abounded in milk, were placed between the fore-limbs. The flesh and milk resembled those of horned cattle, indeed in Steller's opinion surpassed them. The sea-cows were almost constantly employed in pasturing on the sea-weed which grew luxuriantly on the coast, moving the head and neck while so doing much in the same way as an ox. While they pastured they showed great voracity, and did not allow themselves to be disturbed in the least by the presence of man. One might even touch them without their being frightened or disturbed. They entertained great attachment to each other, and when one was harpooned the others made incredible attempts to rescue it."

Fig. 11.—"Seal-rookery" on St. Paul's Island, one of the Pribilov Islands.

We give a sketch of the sea-cow (Fig. 10), as also of the "rookery" of the sea-bears, still found in abundance on St. Paul's Island (Fig. 11).

But we must take leave of a work abounding in interest, and in every way worthy of the important expedition of which it is the outcome.

NOTES

ONCE more we are glad to chronicle the opinion of a prominent politician on the value of science in education. The unanimity of our public men on this point is gratifying, and is a hopeful change from the ignorance of a few years ago. Sir Stafford Northcote, on Tuesday, in distributing the prizes to the students of Exeter School of Science and Art, maintained that the teaching of science cannot be begun at too early an age, as it is now recognised that a knowledge of science is indispensable in all handicrafts. Whilst acknowledging the great value of central agencies in London, yet he thought it desirable that still greater encouragement should be given to the establishment of museums and to the promotion of scientific research in the provinces. Of course, Sir Stafford stated, the great end attained by science classes was not so much the knowledge of a particular study as the development of the powers of the human mind, and training men to apply the utmost reasoning powers to the everyday work of life. It was the development of this mental vigour that would maintain the supremacy of the English race.

FROM the Report of Kew Gardens for 1880 we learn that the number of visitors during last year was 723,681, being an increase of 154,547 over the previous (very inclement) year, and nearly the same as in 1878. Only a comparatively small proportion of visitors take advantage of the early opening on bank-holidays. The scientific lessons given to the young gardeners have been well attended and successful. The Reports from Indian and Colonial Botanical Gardens are specially favourable this year. "A great increase of activity, arising from a variety of causes, has characterised almost all these institutions with which we are in regular correspondence, entailing a very great extension of the official work transacted at Kew, independent of the purely administrative work of the establishment itself." The numerous experiments described in the Report on various economical plants, both in our Colonial Gardens and at Kew itself, prove the great importance of the work carried on at the establishment to the whole empire. The addition of the Economico-botanical collection from the Indian Museum was a notable event of the year, adding so greatly to the resources of the establishment, and entailing much additional work. Other important additions were the collections of the late Prof. Schimper of Strassburg, and General Munro, C.B. It is to be regretted that Government declined to grant a small retaining fee for an entomologist, whose services are indispensable to such an institution as Kew. Mr. R. McLachlan, F.R.S., has hitherto acted as consulting entomologist without fee.

THE Marchese Corsi-Salviati has presented to the Royal Gardens life-size distemper drawings of the gigantic Aroid discovered by Beccari in West Sumatra, and described by him under the name of *Amorphophallus Titanum*. The dimensions of this plant are probably the most gigantic assumed by any herbaceous plant in one season's growth. The underground tuber is 5 feet in circumference. This produces, except when flowering, a single leaf whose stem is 10 feet high; above, this divides into three branches, each as thick as a man's thigh, and the ultimate segments of the much-divided leaf cover an area of 45 feet in circumference. The inflorescence is on a corresponding scale. The drawings are for the present hung for exhibition in the Wood Museum (No. 3).

THE submarine cable between Dover and Calais was carried out during the month of December, 1851, just thirty years ago, and it was on the 31st that the first message was sent from France to England and the traffic opened to the public. The first message was handed to Louis Napoleon, then Prince-President of the French Republic. It was simply a congratulatory salutation. The second was sent by an English banker to his correspondent in Paris, and related to the price of Consols. The Paris firm sent in return the Côte de la Bourse. This exchange of messages, including conveyance to the several offices, did not take more than an hour. Before regular messages were sent experimental sparks were tried. The first which came over from the French shores fired an English gun which saluted the Duke of Wellington when leaving Dover by an express train. It was the last time he visited the place in his capacity of Lord Warden of the Cinque Ports.

MUCH has recently been written on the labours of medical women in India, and we find that such work is not without its reward also in China. According to the *Celestial Empire*, in the summer of 1879 the wife of Li Hung Chang, the great Viceroy of Chihli, was dangerously ill at Tientsin, and foreign medical assistance was called in. Chinese etiquette forbade the two doctors engaged obtaining sufficient knowledge of the case for treatment, and Miss Howard, an American lady with a medical diploma, was at once called in. Under her care Lady Li soon recovered. The result of this successful treatment of the illustrious Chinese lady was the establishment of a large hospital, under a foreign physician, the funds for which were provided by voluntary contribution from the native literati and gentry. The institution has just been opened by the Viceroy himself. When the news of Miss Howard's success reached America a wealthy gentleman of Baltimore subscribed funds to build a hospital for Chinese women at Tientsin, and the two buildings—one erected by Chinese, the other by American philanthropy—now stand side by side in that town. Li Hung Chang and his lady have both presented commemorative tablets to the hospital. One of them runs thus: "The skilful statesman and the skilful physician are alike in this: that they give their thought to cure what is ill. In the act of administering government and of dispensing cures, what hinders China and other lands from being one family?"

M. LISTON having made a series of very interesting observations on the temperature of water and on the conditions of freezing and thawing of a salted lake, Kupalnoye Ozero, in the province of Orenberg, Dr. Woeikoff contributes to the *Archives des Sciences Physiques et Naturelles* a note, with some remarks of his own on these observations which appeared in the eighth volume of the *Memoirs* of the Russian Geographical Society. This Lake Kupalnoye has a surface of 473 square metres and a depth of 1·42 metres, and its water contains 16 per cent. of salt, its bottom being covered with mud very rich in sulphide of hydrogen. The temperatures of the air having been, during the month of January, 1879, from $-6°·3$ to $-28°·2$ Celsius, with one interruption, when the thermometer reached for one day $0°·2$; the temperature of the water at the surface was from $-3°·4$ to $-13°·0$, and at the bottom, from $-3°·8$ to $-12°·8$. On December 27, with a temperature of air as low as $-21°$, the lake was covered with a viscous ice, which soon began, however, to thaw when the temperature of the air rose to $-6°$, and the temperature of water was as low as $-7°·8$. On January 3 all ice had disappeared, but the temperature of the water was still $7°·2$ below the freezing point. On January 11, the temperature of the air being $-22°$, and that of water being $-9°·8$ at the surface and $-5°·6$ at the bottom, the lake began again to be covered with viscous ice, and soon froze, the ice having a thickness of 38 millimetres, which thickness reached 153 mm. ten days later. But the remainder of the water was still unfrozen, notwithstanding that its temperature regularly decreased to $-10°$ on January 17, and even $-12°·8$ on January 30. It was never observed before, M. Woeikoff says, in laboratories that salt water was cooled below $-4°$, without being frozen, and here we have salt water which remains unfrozen at 13° below zero. However, former experiments, especially those of M. Zöppritz, proved that there is no diffusion of salt before congelation; it seems that in Lake Kupalnoye there is such a diffusion of salt towards the lower strata of water, even before the freezing be-

gins; otherwise it would be difficult to explain how colder water might remain on the surface, were it not for the greater amount of salt in the lower strata. It was always difficult to explain, M. Woeikoff observes, how ice is formed on the surface of oceans, the temperature of the maximum of density being lower than that of the congelation; but the question is complicated in oceans by many causes, and therefore M. Woeikoff asked M. Liston to make observations on a salt lake: but Lake Kupalnoye contains too much salt to be compared with oceanic water, and thus it would be desirable to make experiments on this subject on large tanks filled with salt water, and exposed during the winter in rough climates to the action of low temperatures and of radiation.

In the last number of the Geneva *Archives des Sciences Naturelles*, M. W. Meyer gives an account of the applications of the micro-telephone in the Observatory of Geneva for the transmission of the beats of a clock to observers occupied in different rooms of the Observatory. The experiments have been carried on for eighteen months, and although at first there were many difficulties, satisfactory results have been reached. During last year all comparisons of clocks were made by means of the micro-telephone, with the same accuracy as if they had been made directly. The average error of each observation does not exceed 0·06 of a second, and the constant error, deduced from fifty-nine series of observations, is very small (0·001 of a second). Another very interesting experiment was made in connection with the determination of longitudes between Vienna and Geneva, which was undertaken by MM. Oppolzer and Plantamour. By a new application of the microphone, M. Meyer caused the beats of the Observatory clock to be inscribed automatically on a chronograph; and afterwards, by putting this clock into communication with the Vienna Observatory, he made it inscribe its beats automatically on both chronographs, at Vienna and at Geneva, avoiding thus the auxiliary movement which usually establishes the contact in electrical clocks, and may be a cause of inaccuracy. MM. Plantamour and Oppolzer, being both at the time in Vienna, were able to ascertain the accuracy of this new combination, and they afterwards made use of it for the comparison of the Geneva clock with the electrical chronometer. A few improvements in the microphone add very much to the accuracy of the signals and the ease with which they are transmitted to the chronograph.

On the sensitive surface of the body small spaces (it is known) can be distinguished within which two or more stimuli appear as one or simple; these vary in size and form in different parts. The retina must here be included. Now, the rods and cones forming the mosaic of the retina were recently counted by Herr Salzer, and in the central and most sensitive part—the yellow spot, where are only cones—he found a hundredth of a square millimetre to contain 132 to 138 of these. Dr. Du Bois Reymond has lately tested by experiment the supposition that these elements correspond to the "circles of sensibility" for the retina. If so, the number of light-points which, on the same extent of retinal surface (0·01 sq. mm.) give separate visual impressions, should correspond to Salzer's number of cones. The manner of experiment was this: The observer looked through a tube, blackened interiorly towards a perforated screen which could be shifted in the line of a beam of reflected sunlight coming towards the eye. The screen had, in a frame, a piece of tinfoil 5 ctm. square, perforated regularly with a fine sewing-needle in 460 places. This, while looked at, was gradually withdrawn in the line of sight. A point is reached, at which the light-points tend to unite in short lines; with further removal the lines are continuous, as in a grating; and with still further, the distinction of lines is lost. The distances corresponding to such effects were noted, and again, in bringing the screen back. The results are considered to confirm the view under trial, viz. that the number of circles of sensibility in the yellow spot is equal to the number of cones. When there were seventy-four light-points (or half the number of cones) in 0·01 sq. mm., they could just be distinguished, and beyond 149 the lines disappeared.

In a recent number of *Naturen*, Prof. Axel Blytt concludes the highly interesting series of papers in which he has at some length expounded his theory of the immigrations into Norway of different floras during early dry and wet periods. On carefully examining the oldest Norwegian turf bogs, he finds, as Prof. Steenstrup has shown in Denmark, that four distinct turf layers may be traced between which there are frequently two, or even three, equally distinct deposits, composed of the roots and other remains of trees. The latter are found *in situ*, and by the undisturbed condition of the turf-beds above and below them they afford a conclusive proof that such severed trunks cannot have been cut down by human agency. These separate tree beds the author regards as mementoes of long periods of dryness, which may have endured for thousands of years, and during which the formation of turf was arrested, to be resumed again when a wet period supervened. Such interrupted periods of dryness and wet he considers to be closely related to the several long interrupted glacial periods, which, according to Geikie, have succeeded one another. In accordance with Herr Blytt's view the close of the first glacial age was followed by a dry period in which an Arctic flora appeared in Scandinavia, traces of which, as leaves of *Dryas octopetala* and *Salix reticulata*, have been found in the clay underlying the bogs in Denmark and Southern Sweden, in the latter of which the same flora is to be seen interposed between two ancient moraines. The boreal flora, the author is of opinion, we may refer to a dry period, characterised by great summer heat; and in the deposits belonging to this age we find abundant remains of such deciduous trees as, *e.g.* the hazel and the *Prunus avium*, which are now of rare occurrence in Norway, while many other vegetable forms represented in these beds have been long extinct. The differences observable in the bogs of Denmark and Norway Herr Blytt refers to the fact that while the former has undergone very little if any alteration of elevation, the latter has risen since the glacial age 600 feet above the level of the sea. In Norway the formation of the turf beds may be gauged by their varying elevations. Thus in South-East Norway, where the old sea-level has been raised to a height of 600 feet, the turf is from 20 to 26 feet deep, while at low levels, as 30 feet above the strand, the bogs are seldom more than from 2 to 4 feet deep. The author believes that we are justified in expecting that a more careful working out of the theory of the alternation in early times of dry and wet periods will help to elucidate many hitherto unexplained geological and botanical relations, including the distribution of plants; and he considers it probable that the temperature of the ocean, on which climate so largely depends, may similarly be subjected to periodic changes dependent on cosmical laws not less firmly fixed than those which control the movements of the planetary worlds.

We have received from the editor of the *Natural History Journal* various forms for the entry of observations on meteorology and natural history, which are issued to their correspondents in different parts of the country, the meteorological forms being returned to Mr. J. E. Clark, 20, Bootham, York, while those referring to natural history are communicated to Mr. F. A. Lees, Wetherby, Yorkshire. The proposed meteorological observations are fairly satisfactory as regards the natural phenomena in connection with which they are made. The mean date of flowering of each of the thirty selected wild plants for the last three years is given, a feature in the forms well calculated to awaken and sustain the interest of the observers. By these observations carefully made and recorded from year to year

important data will be collected of no little practical and scientific value.

THE Perthshire Natural History Society has had a most successful bazaar in aid of its Natural History Museum, for which it has now secured in all 3300*l*. As they already have a building, the Society ought soon to be able to show an excellent local museum, and make a fair start in the educational enterprise which they have in view. Did "John Stewart's Wines and Spirits," "B. Smith's Sparkling Burgundy," "Peter McIntyre's Buns and Shortbread," "Donald Laing's 2*s*. Tea of Extraordinary Quality," and such like articles, form part of the exhibits at the bazaar? We would infer as much from the style in which the programme is printed.

THE fifth associated *soirée* of the Literary, Scientific, and Art Societies of Liverpool took place on the 21st inst. at St. George's Hall, under the presidency of the Mayor of Liverpool. Of the societies represented, no less than nineteen have distinctly scientific objects, and number 2700 members. In the objects exhibited in the Great Hall were many of considerable biological and geological interest, especially entomological specimens from the neighbourhood of Liverpool, collected by the Rev. H. H. Higgins, and a set of types of the genus *Nassa*, arranged and named by Mr. F. P. Marrat, of the Free Museum, who has done much to elucidate this group of Mollusca. Numerous lectures were given during the *soirée*; those of scientific interest were—"On the Storage and Transmission of Electric Force," by Mr. Fletcher, H.M. Inspector of Alkali Works; "On the Mersey Tunnel, and its Geological Aspects," by Mr. De Rance, H.M. Geological Survey; "On Life at Great Depths in the Ocean," by Prof. Herdman; "On the Life-History of Shell-Fish," by Dr. Hicks. Prof. Herdman described several new forms of life obtained by the *Challenger*, while Mr. De Rance foretold a probably successful termination to the Mersey Tunnel, now one-quarter completed. Nearly 4000 people attended the *soirée*.

WE are glad to see that a Natural History Society has been established in North London, under the name of the "North Middlesex Natural History Association." A Society of this description was much needed in the neighbourhood, and there is, therefore, every prospect of its doing useful work. The objects of the Association will be the formation of a natural history museum, and a library for reference and circulation among members: also the diffusion of natural history knowledge by means of lectures, papers, discussions, &c. It is also proposed to organise field excursions during the summer months. The meetings are held every Tuesday evening between the hours of eight and eleven o'clock p.m. The Secretary is Charles M. Allen, 26, Ingleby Road, Grove Road, Holloway, N.

THE President of the Royal College of Physicians has appointed Dr. George Johnson, F.R.S., to deliver the Harveian Oration.

THE balloon which was seen in the neighbourhood of Santander in Spain, and which was conjectured to be that in which Mr. Powell was carried off, was probably, according to M. W. de Fonvielle, a French meteorological balloon, sent up by the Paris aëronauts equipped to register the phenomena of the upper atmosphere, and with a polyglot request that it be forwarded by the finder to the address given.

TWO earthquake shocks were felt on the 18th inst. in Switzerland, at Bers, Vevey, Lausanne. A few days previously oscillations were observed in Neuchatel, the Valais, and other parts of Switzerland.

THE long-continued eruption of Mount Vesuvius has within the last few days assumed large proportions. Copious streams of lava have been flowing in an easterly direction. It is noteworthy that this increased activity was preceded by sensible seismic agitation of the soil in the neighbouring provinces.

THE new number of the *Proceedings* of the Bristol Naturalists' Society (vol. iii. part ii., Bristol, Fawn and Son) contains some useful papers. We may mention the following:—On the breathing of aquatic larvæ, by W. J. Fuller; On the preparation of a local flora, by J. Walter White; The boulders of the Bromsgrove district, by Oliver Giles; Catalogue of the Lepidoptera of the Bristol district, by A. E. Hudd; Fungi of the Bristol district, by Cedric Bucknall; A naturalist's rambles in Guernsey, by Adolph Leipner; Recent investigations on the cause of storms, by G. F. Burder; papers on Binaural Audition and the Phenautograph, by Prof. S. P. Thompson; and the flora of the Bristol coal-field, by J. Walter White, Part I. Thalamifloræ.

A REPORT from the German Fisheries Union states that during the season 1880–81 no less than 6,151,036 fish ova were artificially hatched, and with the young brood various German rivers were stocked. Amongst them were 1,792,000 salmon, all from the Rhine (with the exception of 18,000 from Pomerania), 295,000 Californian salmon (imported direct from America), 183,500 sea trout (*Trutta trutta*), 6000 *Trutta lacustris*, 46,000 *Trutta fario*, 270,000 *Salmo salvelinus*, 48,536 American trout, 152,000 *Thymallus vulgaris*, 657,000 *Gymnothorax muræna*, 1,810,000 *Coregonus Wartmanni*, 335,000 eels, 151,000 American eels, and 720,000 carp. The results of the Society's efforts become more and more apparent every day in the largely augmented receipts of German fisheries generally.

ON Wednesday, December 21, diplomas of the Royal Agricultural College, Cirencester, were granted to four candidates, and the sessional certificates and prizes distributed.

ON April 10, 1882, the second International Congress for Ethnographical Sciences will be opened at Geneva. The organisation of the Congress is in the hands of M. G. Becker at Lancy (Geneva), the delegate of the Swiss Ethnographical Institute. All who wish to participate in the Congress must send their names to him or to the delegates of the countries they may reside in. The Congress will be divided into seven sections:—(1) Origin and migrations of peoples; (2) Ethnology; (3) Descriptive ethnography; (4) Theoretical ethnography; (5) Manners and customs; (6) Political ethnography; (7) International law. Delegates have already been announced from the following countries:—France, Belgium, England, Luxemburg, Sweden and Norway, Russia, Germany, Roumania, Greece, Italy, Spain, Portugal, Switzerland, Turkey, Egypt, British India, Japan, Canada, the United States, Peru, Australia, and the Argentine Republic.

THE *Transactions* of the Epping Forest Field Club contain some unusually interesting papers. In parts 4 and 5, for example, vol. ii., we have, among others, the following papers: "Is *Vanessa polychloros* the prototype of *Vanessa urticæ*?" by W. White; "The Evolution of Fruit," by Prof. Boulger; "The Developmental Character of the *Larvæ* of the Noctuæ, as Determining the Position of that Group," by Raphael Meldola; "Infusoria, what are They?" by W. Saville Kent; "Report on the Excavation of the Earthwork known as Ambresbury Banks, Epping Forest, by Gen. Pitt-Rivers." Evidently this young Society is doing good work.

THE additions to the Zoological Society's Gardens during the past week include a Malbrouck Monkey ♀ (*Cercopithecus cynosurus*) from West Africa, presented by Mr. C. A. Rose; a Chilian Teal ♂ (*Querquedula creccoides*) from Chili, presented by M. J. M. Cornely; a Kite (*Milvus ictinus*), European, pre-

sented by Mr. G. H. Tod-Heatley; a Rhesus Monkey ♀ (*Macacus erythræus*) from India, a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, deposited; a White-browed Amazon (*Chrysotis albifrons*) from Honduras, a White-headed Parrot (*Pionus senilis*) from Mexico, a Javan Parrakeet (*Palæornis javanicus*) from Java, two Chestnut-breasted Ducks (*Anas castanea*, ♂ ♀) from Australia, a Germain's Peacock Pheasant ♂ *Polyplectron germaini*) from Cochin China, a Black-throated Diver (*Colymbus arcticus*), two Oyster-catchers (*Hæmatopus ostralegus*) British, a —— Deer ♂ (*Cervus* sp. inc.) from Patagonia, purchased; four Undulated Grass Parrakeets (*Melopsittacus undulatus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE SATELLITES OF MARS.—The following Greenwich times of elongations of these satellites are taken from an ephemeris contributed by Prof. Pritchett to *Science* of November 26. At elongation *Deimos* is distant about 52″ from the planet's centre and *Phobos* about 21″; the angle of position, 246°. 5h. 13m. are added to the Washington mean time, for difference of longitude and aberration-time:—

Deimos.

	h. m.		h. m.		h. m.
Dec. 30,	11 57 W.	Jan. 2,	15 36 E.	Jan. 4,	13 0 W.
Jan. 1,	9 20 E.	3,	6 44 W.	6,	10 24 E.

Phobos (W. elongations).

	h. m.		h. m.		h. m.
Dec. 30,	8 16	Jan. 2,	12 46	Jan. 5,	9 38
31,	7 13	3,	11 44	6,	8 36
Jan. 1,	6 10	4,	10 41	7,	7 33

COMET 1881 *g* (SWIFT, NOVEMBER 16).—From observations between November 22 and December 12, Herr J. Palisa has calculated the following orbit of the comet: we express the elements in the form usual in the Catalogues:—

Perihelion passage 1881, November 19·9987 Greenwich M.T.

	° ′ ″	
Longitude of perihelion	63 17 57	M. Eq. 1881·0.
,, ascending node	181 21 41	
Inclination	35 11 54	
Log. perihelion distance	0·284788	

Motion—retrograde.

There is still a certain resemblance to the orbit of the first comet of 1792, discovered by Miss Caroline Herschel, as last calculated by Mechain, but the differences in the elements would not be accounted for by perturbation in the interval, so that it is probable the comets are distinct. Maskelyne's observations in 1791-92 will be found in his third volume in a form that will admit of a new reduction.

THE COMETS OF SHORT PERIOD.—No one of the known comets of short period is due at perihelion in the year 1882. The next to return may probably be that discovered by Tempel in July 1873, at the end of the year 1883, and about the same time D'Arrest's comet will be round again. Brorsen's comet follows in the autumn of 1884.

VARIABLE STARS.—The following are Greenwich times of heliocentric minima of Algol, calculated upon similar data to those used for Prof. Winnecke's ephemeris for 1881:—

	h. m.		h. m.		h. m.
January 3,	16 18·9	January 12,	6 45·5	January 29,	11 38·9
6,	13 7·7	23,	18 1·1	February 1,	8 27·8
9,	9 56·6	26,	14 50·0		

Minima of S Cancri occur on January 19, at 13h. 1m., and February 7, at 12h. 16m. A maximum of the "crimson star" R Leporis may be expected about January 19; the period from the last fifteen years' observations is close upon 436½ days.

We may once more draw attention to the star with which Encke's comet was compared by Rümker at Paramatta on June 19, 1822, and which is certainly variable to a considerable extent. Rümker estimated it between the fourth and fifth magnitude; Gould says 6·0 in the *Uranometria Argentina*; the star is 6·5m. in the *Durchmusterung*, but has been several times noted as low as the eighth magnitude: perhaps systematic observation may show that the period is not a long one. The position of this star for 1882·0 is in R.A. 7h. 23m. 21s., N.P.D. 91° 39′·8.

GEOGRAPHICAL NOTES

INFORMATION has been received from Tromsoe which augurs well for the success of Mr. Leigh Smith's present voyage. Capt. Isaaksen, of the Norwegian whaler *Proven*, saw the *Eira* on June 30 at Matushin Straits at the edge of the ice, a few miles from the coast. On July 2 he again saw the *Eira* steaming southward, and he concludes that Mr. Smith failed to force his way along the coast of Nova Zembla. It is supposed that he again failed to pass Kara Straits, as he was afterwards seen bearing north from Gooseland. Capt. Isaaksen says that the ice was in about its usual position in June and July, but on August 8 it had all gone, he did not know where or how. On the 16th of that month there was no ice twenty miles north of Nova Zembla, but a heavy sea was running from the north. This conclusively shows that the sea was open for a very considerable distance, probably as far as Franz Josef's Land, which Capt. Isaaksen feels certain Mr. Smith has reached, and in such circumstances he would not be astonished if tidings came of his having reached a point very much nearer the North Pole this year. As might have been expected, the Russian Government and Mr. Gordon Bennett are doing everything possible to succour the people of the crushed *Jeannette*; we hope they will soon be all safe in Western Europe.

DR. STECKER, the companion of Dr. G. Rohlfs, writes on June 21 to the editor of *Petermann's Mittheilungen*, from Debra Tabor, on the results of his last journey to Lake Tana. He has explored all the lake, visited the mountains on its shores, and prepared a detailed map of this basin, which covers a surface of 2980 square kilometres, the level of which is 1942 metres above the sea, and which is 30 to 72 metres deep. The map will be the more welcome as Dr. Stecker says that all former maps of the Gorgora Mountains, situated north of the lake, and of its southern shores, are quite wrong. Dr. Stecker is satisfied with the reception he received during his journey from the native rulers, and especially from the Negus, who promises to let him go to Kaffa. During his stay at Lake Tana Dr. Stecker made interesting collections of plants, insects, fishes, and molluscs, and he discovered in the Gorgora Mountains unmistakable proofs of volcanic activity: eruptive cones, a crater, and a mighty lava stream, all probably recent, as in the volcanic rocks, he has found inclosed remains of a mollusc which still inhabits the waters of Laka Tana. After the end of the rainy season he proposes to explore the negro tribes who live west of Lake Tana, and then to travel either to the mouth of the Juba River or to Zanzibar *viâ* Lake Samburu, Mounts Kenia and Kilimangaro.

THE expedition led by Lieut. Holm, and sent out early in the summer by the Copenhagen Commission for the geological and geographical investigation of Greenland, has just returned. The expedition proceeded to the southernmost part of Greenland; they succeeded in circumnavigating the large islands on the southern coast, and in determining the exact position of Cape Farewell. The land itself was investigated as far as line drawn from the Tasermint Fjord on the west coast, to the Lindenows Fjord on the east coast. It contains magnificent alpine scenery with enormous glaciers, particularly on the western side. The low-lying eastern part is covered with a layer of ice and snow, which forms hills and valleys, following the soil underneath; here and there mountain peaks rise above the immense winter landscape.

THE *Oesterreichische Monatsschrift für den Orient* for November contains a paper by von Hellwald on the Gilyaks of Eastern Siberia. They inhabit the districts of the Lower Amour, the coast of the Straits of Tartary, and the northern part of Saghalin. Estimates of their numbers vary from 8000 to 3000. Col. Wenjukow thinks they form a special branch of the yellow race, but not a subdivision of the Tungusic stock. Their language, he says, has no resemblance to the Tungusic, and their physiological structure betoken a more powerful and energetic race than the neighbouring Magunes, Samagry, &c. Ravenstein also distinguishes the Gilyak tongue, which is rich in monosyllables, from the Tungusic, and others distinguish it from the Aino, with which it has been sometimes connected. They are said to have oblique eyes, prominent cheek-bones, and scanty beards; the

hair is dark and thick, the nose flat, and the chin pointed. A skull which Barnard Davis succeeded in sending to England was found to have a capacity of 1638 cubic centimetres, with horizontal and vertical indices of 77·3 and 78·3 respectively. They have the reputation of being a bloodthirsty and inhospitable people, but they have now succeeded better than any of the neighbouring tribes in drawing closer to the Russians. They frequently change their paganism for the Russian Orthodox Church. The Japanese, with whom they traded in the southern part of Saghalin, have had no great influence over them. Sometimes they live in houses which are built on piles raised some distance above the ground, with a platform, or balcony around, on which they lay their sledges, nets, &c. From the roof are suspended hundreds of salmon, put there to be smoked and dried. The men pass most of the time away from their families, fishing or hunting. They are especially fond of the dolphin, but as they have but bad weapons of the chase, they rarely succeed in catching this fish. When they do, however, the occasion is kept as a festival. As with most of the aborigines of North-Eastern Asia, they reverence the bear as a divinity, but it is nevertheless almost invariably slaughtered. Their proceedings at the festival of the bear resemble those of the Ainos of Yezo, drunkenness being the order of the day. The religion of the Gilyaks is Shamanism with all its superstitions. They will allow no one to take a spark of fire, even in a tobacco-pipe, from their huts, believing that ill-luck and misfortune will follow. The bodies of the dead are burned, and a small house erected above the ashes, while a favourite hound is slaughtered on the grave. The Gilyaks in Saghalin differ in some respects from those on the mainland. Their mode of living differs little from that of the Ainos. Marriage is not permitted among members of the same family; wives are purchased, but also captured. The Japanese traveller, Mamia Rinso, who thoroughly examined the whole of Saghalin and the neighbouring coast about the beginning of this century, says that polyandry existed amongst them. They are the most superstitious of all the Tungusic tribes in the Amour region, as well as the most cruel in their customs.

THE United States war-steamer *Palos* has been engaged for some time past, by order of the American Government, in carrying out a series of observations in China and Japan with the object of ascertaining the correct latitude and longitude of certain important points. The position of Wladivostock was determined by Russian engineers some years ago, and the object of the present expedition is to settle those of the chief centres between that place and Madras, *e.g.* Nagasaki, Amoy, Shanghai, Hongkong, and Singapore. The positions of the first three have been determined, and it is said do not show any great discrepancy with those hitherto accepted.

THE December number of the Geographical Society's *Proceedings* opens with Mr. F. A. A. Simons' paper on the Sierra Nevada of Santa Marta and its watershed, accompanied by a good map of the region from his own survey. Mr. Delmar Morgan contributes a paper on steppe-routes from Karshi to the Amu-daria, being an annotated rendering of one by M. Maief in the Russian Geographical Society's *Isvestia*. In the Geographical Notes the new Russo-Chinese frontier is described, and there is an interesting note on the old map of Djungaria by the Swede Renat, recently discovered in the library of Linköping. M. Wiener's discovery of the Samiriá tributary of the Upper Marañon is also referred to, and it is stated that he has constructed a map of this almost unknown region. Perhaps the most interesting item in the whole number is the short letter from Capt. Gray, of Peterhead, on the recent advance of the Polar ice in the Greenland and Spitzbergen Sea, with its accompanying ice-chart. A long report on the Venice Congress and Exhibition is furnished by Capt. A. W. Baird, R.E., and is the only one, so far as we know, which has yet been published.

THE last *Bulletin* of the Commercial Geographical Society of Bordeaux contains some notes on M. Ch. Wiener's extensive explorations on the tributaries of the Upper Amazon by a Peruvian, Sr. M. Albornoz, and observations by M. Raeckelboom on the country, &c., between Susa and Kairwan.

DR. LENZ ON THE SAHARA

IN a paper which Dr. Oscar Lenz contributes to the *Zeitschrift* of the Berlin Geographical Society, he gives an authentic account of the results of his journey across the Sahara, from Tanger to Timbuktu, and thence to Senegambia. The real journey was begun at Marrakesh, at the northern foot of the Atlas Mountains, where Dr. Lenz laid in his stores of provisions and changed his name and dress, travelling further under the disguise of a Turkish military surgeon. He crossed the Atlas and the Anti-Atlas in a south-western direction. The Atlas consists, first, of a series of low hills belonging to the Tertiary and Cretaceous formations, then of a wide plateau of red sandstone, probably Triassic, and of the chief range which consists of clay-slates with extensive iron ores. The pass of Bibauan is 1250 metres above the sea-level, and it is surrounded with peaks about 4000 metres high, whilst the Wad Sus Valley at its foot is but 150 metres above the sea. The Anti-Atlas consists of Palæozoic strata. On May 5, 1880, Dr. Lenz reached Tenduf, a small town founded some thirty years ago, and promising to acquire great importance as a station for caravans. The northern part of the Sahara is a plateau 400 metres high, consisting of horizontal Devonian strata which contain numerous fossils. On May 15 Dr. Lenz crossed the moving sand-dunes of Igidi, a wide tract where he observed the interesting phenomenon of musical sand, a sound like that of a trumpet being produced by the friction of the small grains of quartz. But amidst these moving dunes it is not uncommon to find some grazing-places for camels, as well as flocks of gazelles and antelopes. At El Eglab Dr. Lenz found granite and porphyry, and was fortunate enough to have rain. Thence the character of the desert becomes more varied, the route crossing sometimes sandy and sometimes stony tracts or sand-dunes, with several dry river-beds running east and west between them. On May 29 he reached the salt works of Taudeni, and visited the ruins of a very ancient town, where numerous stone implements have been found. Here he crossed a depression of the desert only 145 to 170 metres high, while the remainder of the desert usually reaches as much as 250 to 300 metres above the sea-level; and he remarks that throughout his journey he did not meet with depressions below the sea-level. The schemes for flooding the Sahara are therefore hopeless and misleading. The landscape remained the same until the wide Alfa fields, which extend north of Arauan. This little town is situated amidst sand-dunes devoid of vegetation, owing to the hot southern winds. Four days later Dr. Lenz was in Timbuktu, whence he proceeded west to St. Louis. During his forty-three days' travel through the Sahara Dr. Lenz observed that the temperature was not excessive; it usually was from 34° to 36° Celsius, and only in the Igidi region it reached 45°. The wind blew mostly from north-west, and it was only south of Taudeni that the traveller experienced the hot south winds (*edrash*) of the desert. As to the theory of north-eastern trade-winds being the cause of the formation of the desert, Dr. Lenz remarks that he never observed such a wind, nor did his men; it must be stopped by the hilly tracts of the north. Another important remark of Dr. Lenz is what he makes with respect to the frequent description of the Sahara as a sea-bed. Of course it was under the sea, but during the Devonian, Cretaceous, and Tertiary periods; as to the sand which covers it now, it has nothing to do with the sea: it is the product of destruction of sandstones by atmospheric agencies. Northern Africa was not always a desert, and the causes of its being so now must be sought for, not in geological, but in meteorological influences.

SCIENTIFIC SERIALS

Journal of Anatomy and Physiology, vol. xvi., part 1, October, 1881, contains—Dr. D. J. Cunningham, on the relation of nerve-supply to muscle-homology.—Dr. Gibson, the action of duboisia on the circulation.—J. F. Knott, the cerebral sinuses and their variations.—Dr. G. Barling, primary growth from bone, resembling in some of its features scirrhus carcinoma of the breast.—Doctors George and F. Elizabeth Hoggan, the comparative anatomy of the uterine lymphatics (plates 1 and 2).—Dr. H. Ashby, transposition of the aorta and pulmonary artery in a child of seven months.—Dr. W. Stirling, some points in the histology of the newt, and on the nerves of the lungs of the newt (plates 3 and 4).—Dr. Garson, on pelvimetry (plate 5).—Prof. Turner, cranial characters of the Admiralty Islanders.—Report on physiology, and anatomical notes.

The American Naturalist for November, 1881, contains: W. K. Higley, on the general and microscopical characters of the peach tree affected with the "yellows."—W. H. Dall, on the so-called Chukchi and Namolló people of Eastern Siberia.—W. H. Edwards, the length of life in butterflies.—H. D. Minot notes on the migrations of birds.—V. Havard, on Sotol.—E.

D. Cope and A. S. Packard, jun., on the fauna of Nickajack Cave. Many miles were explored, and no end reached. The invertebrate fauna of the caves proved very considerable, and several new species are described and figured; one of the most interesting is the blind crayfish (*Orconectes hamulatus*, Cope).—Recent Literature, Scientific News, &c.

Rivista Scientifico-Industriale, No 18, October 15.—Malfatti's fossil Italian insects.—On the rectification of the cycloid, by Prof. Dainelli.

Verhandlungen der k.k. geologischen Reichsanstalt, No. 14, September 30.—Inclosures of foreign stones in crystalline limestone, by T. Fuchs.—Picrite-porphyry of Steierdorf, by E. Hussak.—On tentaculites, by O. Novak.—A note on the diluvium of Masenderan in Persia, by E. Tietze.—Travellers' reports.

Journal of the Asiatic Society of Bengal, vol. l. part 2, No. 3, 1881 (October 22).—Geoffrey Nevill, on new or little-known mollusca of the Indo-Malayan fauna (plates 5 to 7).—Dr. O. Feistmantel, a sketch of the history of the fossils of the Indian Gondwána system.—Prof. V. Ball, additional note on the identification of the ancient diamond mines visited by Tavernier.—J. Wood-Mason and Lionel de Nicéville, list of diurnal Lepidoptera inhabiting the Nicobar Islands.

Revue des Sciences Naturelles, tome 1, série 3ᵉ, No. 1, September, 1881, contains:—P. Gazalis de Fondouce, on Tertiary man in Portugal.—Prof. S. Berggren, on the prothallus and on the embryo of Azolla (plate 1).—G. M. Vignier, studies on the formation of tufas of the present epoch.—Dr. P. Amans, anatomical and physiological researches on the larva of *Æschna grandis* (plate 2).—Account of the Zoological Station at Cette.

Revue internationale des Sciences biologiques, October, 1881, contains:—M. Bochefontaine, on the effects of the obstruction of the coronary arteries on the heart's action.—Jules Soury, on the modern doctrine of hylozoism (the doctrine which considers matter as living).—Prof. Hanstein, protoplasm considered as the basis of animal and vegetable life.—Dr. W. Roberts, on the digestive ferments.

THE last number of the *Journal* of the Russian Chemical and Physical Society contains, besides the minutes of proceedings, papers by Prof. Menshutkin, on the etherification of polybasic acids; on the bromides of vinyle, and on cholic acid, by M. Kutcheroff; on the affinities of sulphur with metals, and on the means of discovering cadmium in presence of copper, by M. Orlovsky; and on the potential of hydrostatic pressures, by M. Latchinoff.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 8.—"On the Coefficients of Contraction and Expansion by Heat of the Iodide of Silver AgI; the Iodide of Copper Cu_2I_2; and of five Alloys of these Iodides," by G. F. Rodwell, F.R.A.S., F.C.S., Science Master in Marlborough College.

The experiments herein described are a continuation of those relating to the anomalous expansion by heat of certain iodides, published at intervals during the last five years in the *Proceedings* of the Royal Society. New determinations of the coefficients of iodide of silver are given. Certain physical and chemical properties of cuprous iodide are detailed, and its coefficient of expansion is determined. Five compounds or alloys were prepared, and their physical characteristics examined. They possessed the following composition, and percentage of iodide of silver:—

Composition.	Percentage of Iodide of Silver.
$Cu_2I_2.AgI$	38·2233
$Cu_2I_2.2AgI$	55·3066
$Cu_2I_2.3AgI$	64·9884
$Cu_2I_2.4AgI$	71·2225
$Cu_2I_2.12AgI$	88·1304

They are compared with the five chlorobromiodides of silver previously examined by the author (*Proc.* Roy. Soc. vol. xxv. p. 303), and with the lead-silver iodide alloy last described (*Proc.* Roy. Soc. vol. xxxii. p. 540).

The following are some of the results observed in connection with the new copper-silver iodide alloys:—

"1. The specific gravity varies but slightly, viz. from 5·7302 to 5·6950, and is a little above the mean specific gravity of the constituents."

"2. The melting points are in all cases much lower than that of either iodide of silver or iodide of copper, for while the former is 527° C., and the latter 601° C., the highest melting-point of any one of the alloys is 514° C., and the lowest 493° C.

"3. Some of the alloys possess three points of similar density, and some two, at different temperatures. They are resinous in fracture, and transparent in thin layers. When pulverised they furnish brilliantly yellow powders, unaffected by light.

"4. When heated in a current of carbonic anhydride they volatilise very slowly. Heated in dry oxygen iodine is freely evolved, and oxide of copper appears on ihe surface of the mass. When heated in dry hydrogen hydriodic acid is produced, and the metal is reduced.

"5. The coefficients of expansion of the alloys below the point at which contraction on heating commences, was found to decrease as the percentage of iodide of silver was augmented.

"6. While the iodide of silver commences its considerable contraction at 142° C., the five chlorobromiodides of silver, the percentage of iodide of silver in which varies from 26·1692 to 73·9285, and the lead-silver iodide alloy, the percentage of iodide of silver in which amounts to 33·794, all commenced their contraction at 124° C., that is 18° C. lower, although the coefficients of expansion of the associated bodies necessarily differ. Thus it would appear that 124° C. is the temperature at which iodide of silver commences its passage from the crystalline into the amorphous condition when freed from the attraction of its own molecules, provided no other attraction or influence supervenes; while the attraction exerted when it exists unalloyed with any other substance, and when its molecules are hence much nearer to each other, raises the point at which the change commences to 142° C.

"7. When the same result was looked for in the case of the copper-silver iodide alloys, it was not found. In fact the presence of the iodide of copper, instead of promoting the assimilation of molecular motion and lowering the point at which the change from the crystalline into the plastic condition commences was found to considerably raise it; although the coefficient of expansion of the iodide of copper is lower than that of either chloride or bromide of silver or of the iodide of lead which enter into the composition of the other alloys. Thus:

Percentage of iodide of silver in the copper-silver iodide alloys.	Temperature at which contraction on heating commences.
38·2232	284° C.
55·3066	233°
64·9886	214°
71·2225	199°
88·1304	153°

Hence while 66·206 per cent. of iodide of lead lowered the point of change 18° C., the presence of 61·7767 per cent. of iodide of copper raised it 142° C."

A general discussion of the results is given and the special properties of the alloys described.

Linnean Society, December 15.—G. Busk, F.R.S., in the chair.—Prof. T. S. Cobbold exhibited a large guinea-worm (*Dracunculus*) taken from a pony, and forwarded by Vet. Surg. Frederick Smith from Madras. Only one previous instance of the occurrence of this parasite in the horse has been mentioned, and its authenticity was doubted by Fedschenko and other helminthologists.—Mr. G. S. Boulger brought before the meeting a set of large papier-maché models of insectivorous plants made at Breslau by Herr Brendel under the superintendence of Prof. Cohn. Mr. Boulger explained their adaptation for teaching purposes, and made special referenre by a diagram to the various stages and physiological distinctions of these plants, viz. from simple viscidity of surface to the more complex apparatus in Dionæa and Aldrovanda.—Mr. T. Christy called attention to a volume of the Annual Report of the Commissioner of Agriculture, Washington, U.S. (1879), wherein was embodied much valuable information on the insects and parasites destructive to crops, &c.—Prof. Duncan thereafter gave the gist of a paper on the morphology of the test of the Temnopleuraidæ.—A paper by Dr. Maxwell Masters followed, dealing with a new species of cotton (*Gossypium Kirkii*) from East Tropical Africa. It has an interest historically from being probably the origin of very numerous cultivated varieties. It was obtained by Sir John Kirk growing wild at Dar Salam. Dr. Masters regards it as most nearly allied to *G. barbadense*, which is most

commonly cultivated in tropical Africa; though along the Nile valley *G. herbaceum* is that usually in cultivation. According to authorities, cotton was not cultivated in Egypt in ancient times, and the fact that the varieties now grown there are for the most part forms of *G. herbaceum*, suggests the idea that India is the source whence Egypt has derived the cotton—a notion confirmed by various other considerations. The wild form of *G. herbaceum*, Dr. Masters has previously shown, is probably *G. Stocksii*, Masters, a native of Scinde.—A note on *Abies Pattonii*, Jeffrey, MS. 1851, by Prof. W. R. McNab, was then read. The author mentions that the trees known as *A. Hookeriana* and *A. Pattonii* have been a source of confusion to botanists and horticulturists. Andrew Murray, in 1855, in describing a New North American pine, mixed up the leaf of *A. Pattonii*, Balf., from Mount Baker, with the cone of *A. Hookeriana* from Scots Mountain, Oregon, originally collected by Mr. John Jeffrey. Dr. McNab, in unravelling the error, proposes that as Jeffreys, No. 430, from the Cascade Mountains, named by Balfour *A. Pattonii*, in the Oregon Circular, was unpublished, it should now be referred to *Tsuga Hookeriana*, and the Mount Baker tree he regarded as *T. Pattoniana*.—There followed a paper by Dr. G. E. Dobson, on the digastric muscle, its modifications and functions; and thereafter the eleventh part of the Mollusca of the *Challenger* Expedition, by the Rev. R. Boog Watson, was read in abstract.—Messrs. W. H. Coffin, E. Milner, and S. H. Parkes were balloted for and elected Fellows of the Society.

Mineralogical Society, December 14.—W. H. Hudleston, F.G.S., President, in the chair.—Messrs. H. Baker, F.C.S., and R. Fleming, were elected Members.—The following paper was read:—On some minerals from the sodalite syenite of Julianshaal District, South Greenland, by Johann Lorengen; communicated by Prof. Johnstrup.—Mr. Baring Gould and Mr. Porter Rhodes, who were present as visitors, gave an account of the diamond mine of Kimberley, South Africa, illustrated by photographs of the workings and by numerous specimens, which gave rise to an interesting conversation.

Paris

Academy of Sciences, December 19.—M. Wurtz in the chair.—The following papers were read:—Proofs of the recent formation of the Mediterranean, by M. Blanchard. In the nature and relations of plant species in places more or less apart he seeks evidence regarding changes that have occurred in the configuration of the land. Were the banks of the Mediterranean brought together one might pass from Europe into Africa or into Asia without any trait of nature making one aware of it. Now as very moderate obstacles prevent a dissemination of many plants and animals, the Mediterranean would be absolutely uncrossable by most living species. It is inferred that the sea has been formed in the present age of the earth, when the animals and plants on the coasts were under the same conditions as now. The recent study of the marine fauna, proving that there are few species in the depths, and those present are probably from the Atlantic, is thought confirmative. M. Milne Edwards considered the uniformity of natural productions explained rather by the recent existence of two isthmuses between the northern and southern banks of an older sea, one between Sicily and Tunis, the other between Spain and Morocco. The Mediterranean has probably not been in communication with the Indian Ocean since the Miocene epoch. M. Daubrée also declined, on geological grounds, to accept M. Blanchard's conclusion.—Observations on the decomposition of metallic formiates in presence of water, by M. Berthelot.—On the principle of surfaces of separation, by the same.—M. de Lesseps presented maps and plans of the project of a railway between the Niger and the Soudan, by the Fouta-Djallon. The Fonta-Djallon presents a central plateau 350 km. from the coast and 1000 m. in altitude; five parallel valleys run from it to the coast. The iman of Timbo (in that region) is friendly.—Researches on the fundamental laws of electrodynamics, by M. Le Cordier. This mathematical memoir was deposited as a sealed packet in September.—On a means of preventing the development of phylloxera by turfing the ground in the intervals of the vine-stocks, by M. Bidauld. This proposal is based on the facts that heating of the ground is very favourable to hatching of the apterous, and still more of the winged phylloxera, and that according to MM. Becquerel, bare ground requires in summer a much higher temperature than turfed ground.—Ephemerides of the planet (217) Eudore (continued), by M. Callandreau.—On the introduction of logarithms in criteriums, which determine an upper limit of the number of roots of an equation which are comprised between two given numbers, by M. Laguerre.—On a differential equation of the form $f\left(n\frac{du}{dz}\right) = 0$, by M. Fuchs.—On functions irreducible according to a prime modulus, by M. Pellet.—Theorem of arithmetic, by M. Weil.—Amplitude of diurnal oscillation of the magnetic declination obtained at the Observatory of the Charles Albert Royal College, at Moncalieri, in the years 1879 and 1880, by M. Denza. In agreement with previous data (1871-78) the minimum occurs in the winter months, and the maximum in summer. The values for the summer months are very variable. The mean annual values for the two years are both superior to that for 1878, which, indeed, is the smallest in the period 1870-1881; the minimum seems to have been passed then, or rather between 1877 and 1878.—On the method of M. Lippmann for determination of the ohm, by M. Brillouin.—History of the process employed for direct coppering of cast iron, by M. Weil. He maintains his rights and priority in the invention. His patents date from 1863.—On the diffusion of solids in solids, by M. Colson. When, *e.g.* in a reducing atmosphere, an iron plate is heated in lampblack, not only does carbon pass into the iron, changing it successively into steel and cast iron, but notable quantities of iron are diffused in the carbon. This will occur at a temperature below red. At a low temperature the iron is more easily diffused in the carbon; at a high, the reverse is the case. Nothing of the kind occurs with platinum. For two solids to diffuse into each other, there must be affinity, or more generally, they must react on each other. M. Colson illustrates this, and he describes an experiment establishing the law of the diffusion.—On the temperature of combustion, and on the dissociation of carbonic acid and of aqueous vapour, by MM. Mallard and Le Chatelier.—On chromocyanide of potassium, by M. Moissan.—On the decomposition of metallic formiates in presence of water; production of some crystalline mineral species, by M. Riban.—On a new sub-class of Infusoria, by Mr. Geddes. This relates to curious, small, curved, pear-shaped cells found in the mesoderm of the Planarian *Convoluta*; they have a large central vacuole, and in the wall of this a row of fibrillæ, which, when the cell is in water, are in rapid rhythmic contraction, altering its shape. When in the animal's body, the cell shows but slight contraction. The author thinks these cells parasitic infusoria, and proposes for them the name *Pulsatella convolutæ*; a fourth sub-class, *Pulsatorians*, being here represented.—On a new type of Turbellaria, by M. Silliman. This was got at Roscoff; it is parasitic on a green parasitic nematoid. It is intermediate between Turbellaria and Trematoda, and the author proposes to call it *Syndesmis*. The genital organs are the most remarkable character.—On the live fishes, crabs, and molluscs ejected by the Artesian wells of the Oued Rir (Sahara of the province of Constantine), by M. Rolland. These animals are only for a time under ground in passing from one "bahr" or pond to another.—On the age of the carboniferous limestone of the Central Oural, by M. Grand Eury.—Two posthumous memoirs of M. Delesse were presented: one on the influence of soil on the composition of the ashes of plants, the other on the waters of Savoy.

THURSDAY, JANUARY 5, 1882

ON THE GEOLOGICAL IMPORTANCE OF THE TIDES

IT has naturally been a source of much satisfaction to me that a man as able and eloquent as the Astronomer-Royal for Ireland should have come forward as an exponent of the theory which I have advanced concerning the part played by tides in the history of the earth and the other planets. I cannot but feel therefore that it may seem ungracious on my part to appear as a critic, and to ask Mr. Ball to reconsider some of the deductions which he has made in his Birmingham lecture (see NATURE, vol. xxv. pp. 79, 103). I refer to the geological aspects of the theory. The interest of the subject will, I feel sure, prove a sufficient excuse for my being thus critical.

There is I believe a growing feeling amongst geologists that the extreme uniformitarian view as to geological action requires modification. We find on the one hand the physicist demanding of the geologist that he should hurry on the rate of action, and on the other hand the geologist telling the physicist to moderate his demands. A theory, therefore, which receives much support from purely astronomical considerations concerning the observed configurations of planets and satellites, and which enables geologists to perceive *how* the rate of geological action may have been more rapid in the past, is valuable as a means of reconciliation between two apparently opposed branches of science. All this has been admirably insisted on by Mr. Ball, but I think that in the revulsion from uniformitarianism he has passed considerably too far into the ranks of the opposite school.

Accepting the truth of the tidal mode of evolution of the earth and moon, the question at issue is as to what portion of the series of changes, since the birth of the moon, falls within the region of geological history.

In my own paper in discussing this point, I said :

"There are other consequences of interest to geologists which flow from the present hypothesis. As we look at the whole series of changes from the remote past, the ellipticity of figure of the earth must have been continually diminishing, and thus the Polar regions must have been ever rising and the equatorial ones falling; but, as the ocean always followed these changes, they might quite well have left no geological traces.

"The tides must have been very much more frequent and larger, and accordingly the rate of oceanic denudation much accelerated.

"The more rapid alternation of day and night would probably lead to more sudden and violent storms, and the increased rotation of the earth would augment the violence of the trade winds, which in their turn would affect oceanic currents. Thus there would result an acceleration of geological action."[1]

At the time when I wrote this I contemplated the possibility of the tides having been, in the earliest geological times,[2] perhaps twice or thrice as high as at present, and I now feel inclined to consider this estimate rather as excessive than deficient. But Mr. Ball speaks of tides of over 600 feet as having perhaps occurred within geological times, and I would now ask him to reconsider the probability of this view.

The older geologists attributed the larger part of denudation to the action of the sea, but according to the modern, and undoubtedly the more correct opinion, the denuding action of air and rain, with the aid of rivers and their countless affluents, is of far greater importance. Mr. Ball does not allude to the probable increase of rainfall, but it would, I conceive, be quite as important as the direct tidal action.

If the ordinarily received theory of the trade and antitrade winds be correct, it follows that in similar planets, at equal distances from the sun and with the same depth of atmosphere, the velocity of the wind should vary as the linear velocity of a point at the planet's equator. The planet Jupiter rotates 2·4 times as fast as the earth, and has a radius $10\frac{1}{2}$ times as great; hence if it were not for the greater distance from the sun the trades should blow with 25 times the violence which we observe on the earth. But solar radiation at Jupiter is about $\frac{1}{27}$ of that at the earth. Hence if Jupiter had an atmosphere of the same depth as that of the earth, the trade-winds might blow with about the same violence. If however there be a much deeper atmosphere on that planet, then the amount of solar heat absorbed might be much greater, and the violence of the winds increased. The bands on Jupiter, which are due to the trades and anti-trades, thus afford some evidence that the atmosphere of Jupiter is very deep. It seems, however, quite possible that the violence of the Jovian trades is due partially, or to a great extent, to the heat of the Jovian nucleus.

But now let us return to the case of the earth. The table of numerical values which I have computed (*Op. cit.* p. 494) shows that, when the lunar distance was ten earth's radii (which gives Mr. Ball's tide of 648 feet), the earth must have been rotating in about seven hours. Accordingly it is probable that the trades and anti-trades blew with about $3\frac{3}{7}$ their present velocity. This violence of the general atmospheric circulation to and from the equator, coupled with the rapid alternations of day and night, would undoubtedly give rise to vortical storms of prodigious violence.

Now if this state of things existed in geological history we should expect to find the earlier sedimentary rocks of much coarser grain than the modern ones; but I am not aware that this is the case. Again to withstand such blasts, the earliest trees should have trunks of enormous thickness, and their leaves must have been very tough, or they would have been torn to shreds. There seems to be no reason to suppose that the trees of the carboniferous period present marked peculiarities in these respects.

It is on these grounds that I venture to dissent from Mr. Ball in the geological interpretation to be placed on the tidal theory, and I think we must put these violent phenomena in pregeological periods.

The dispute is, however, only as to the amount of influence, and I cannot learn that geologists are in a position to affirm that in early periods the storms were not say twice as frequent, and the tides twice as high. The

[1] "Precession of a Viscous Spheroid. &c.," *Phil. Trans.* Part 2, 1879, p. 532. It would occupy too much space to reproduce the other comments on the Geological aspects of the theory.

[2] A double tide would (in round numbers) correspond to a lunar distance of 48 earth's radii, instead of the present 60, and to a day of about 16 hours. A double tide gives a quadruple rate of retardation of the earth's rotation.

acceptation of the view, that they were so, would go far to reconcile the discrepant opinions of the geologists and physicists.

There is, as I learn, some slight geological reason for supposing the tides to have been higher in early times, although this interpretation does not seem to have been hitherto attributed to the fact to which I allude. It appears that in the oldest formations there are beds many feet in thickness covered with ripple marks. The preservation of ripples is due to a fortuitous concurrence of causes, and it therefore cannot be asserted positively that if many ripples are preserved the number of ripples formed was great. Such a deduction possesses, however, a considerable degree of probability, and one of the conditions for the formation of many ripples is a great ebb and flow of the tides.

Lyell's interesting observations on the sands in the Bay of Fundy ("Travels in North America," vol. ii. p. 166), where the tide rises through about seventy feet, seem to show that the preservation of superficial marks on sand occurs principally at neap tides, when large areas of sand are exposed for a long time to the sun, after having been covered with water at the spring tide. Now when the tides were twice as high as at present, there must have been 19 or 20 of our present days in the month instead of 27⅓ as at present, and there would be about 38 neap tides in the year instead of about 26.

Since writing the above I have seen Mr. Hull's paper on this subject in NATURE (vol. xxv. p. 177). The evidence which he adduces is of much interest, and if geologists should generally come to recognise the necessity of a powerful denuding agency in order to explain the earlier geological phenomena, such an opinion will stand in direct confirmation of the theory which I have advanced. Notwithstanding what Mr. Hull says, I am still inclined to adhere more to the moderate views maintained above, rather than to admit the extended application of the tidal theory to geology for which Mr. Ball contends. I conceive that a very great acceleration of geological action would result from tides of even one-hundredth of the height portrayed by Mr. Ball, when such tides are accompanied by an intensification of meteorological action.

If Mr. Hull had read my papers, he would have seen that a necessary concomitant of these changes has been a secular diminution of the ellipticity of the earth's figure. For example, when the tides were 600 feet in height, the ellipticity must have been about twelve times as great as at present. Now Sir William Thomson will not allow that there can have been any great change in the ellipticity of the earth's figure since the consolidation of the earth (Thomson and Tait's "Nat. Phil." § 830).

If this opinion is correct, extended geological action, as resulting from the present series of causes, is absolutely excluded. For myself I am not at present able to see the force of his argument, for various reasons on which it is useless to enter here. But it must be admitted that in any contest between him and me the chances of correctness are enormously on his side.

In conclusion I wish to add that in my first paper I probably attributed too much of the changes in the configuration of the earth and moon to the effect of bodily tidal deformation of the earth's mass. The evidence is strong that such tides are now but small, or even scarcely sensible in amount, and accordingly in all probability the later part of the changes must be attributed almost entirely to the effects of oceanic tidal friction, whilst in the earlier part the tides of the solid or semi-solid matter constituting the planet were the more important. It is remarkable that this view enables us to give a satisfactory account of the inclination of the lunar orbit to the ecliptic, as is shown in a later paper.[1]

G. H. DARWIN

EXNER ON CEREBRAL LOCALISATION

Untersuchungen über die Localisation der Functionen in der Grosshirnrinde des Menschen. Von Prof. Sigmund Exner. (Wien, 1881.)

THIS work is an attempt to determine the functions of different parts of the cerebral hemispheres by an examination of the facts of disease alone, independently of physiological experiment. The difficulties which have to be encountered in the solution of the problem by this method are great, and the sources of fallacy numerous. The facts, collected as they must be from the most diverse sources, are not all of the same value, and errors of observation on the score of inaccuracy or incompleteness have to be taken into account and allowed for. The experiments of disease are as a rule rude, and the conditions highly complex. Certain parts of the brain are more liable to disease than others, and one hemisphere more than the other. Besides the lesion actually discovered after death, there may be others not discovered or not discoverable by our present methods, either coincident merely or indirectly connected with the visible lesion; for morbid anatomy and morbid physiology are by no means coextensive. Exactly symmetrical bilateral lesions are extremely rare in disease, and yet such facts are absolutely necessary for the decision of many important questions.

These and many other circumstances render the determination of the functions of the brain from the data of disease alone extremely uncertain, if not impossible. Until the discovery of new experimental methods a few years ago cerebral pathology, except in one or two particulars, chiefly speculative or purely empirical, was practically in a state of chaos. It is only since the introduction of the new doctrines founded on experimental research that the facts of cerebral disease have begun to be investigated and recorded with any approach to scientific accuracy, and order has begun to show itself where formerly all seemed confusion.

Prof. Exner is of opinion that his predecessors have examined the facts of cerebral disease merely with a view of confirming preconceived theories, and have not exercised sufficient discrimination in the selection of the cases they adduce in favour of the propositions they maintain. In this respect particularly he claims superiority over all who have treated the subject before him.

Out of several thousand cases of cerebral disease on record, he has been able to find only 168 instances of

[1] "On the Secular Changes in the Elements of the Orbit of a Satellite, &c.," (*Phil. Trans.*, part ii., 1880, p. 731).

lesion of the cortex capable of being made the basis of reliable inductions.

He has represented together on a series of figures of different aspects of the cerebral hemispheres the position and extent of the lesion recorded in each case; and he has carefully tabulated the symptoms observed, whether positive or negative. In determining the functions of the parts he follows three methods mutually complementary. First, the method of negative instances;—all the lesions being taken together in which a certain function was not affected. Secondly, the percentage method;—the proportion of cases being indicated in which a certain region was diseased, and the relative frequency of the symptom in question. Thirdly, the method of positive instances, *i.e.* all the cases of disease in which a particular affection was observed;—a method used mainly as an adjunct to the other methods, and not of itself of great force. By these methods he arrives at the determination of certain areas or centres which he terms *absolute*, lesion of which always causes the same symptom. He defines more or less vaguely absolute centres for the upper and lower limbs more especially. In addition to the absolute areas he defines a number of *relative* areas, or centres, for other movements, and different forms of sensibility; the relative areas being those in which lesion does not always, but only *frequently*, cause affection of the function with which they are supposed to be in relation.

The elaborate and carefully prepared figures which accompany the work indicate clearly the areas of latent lesions, as well as the position and extent of the absolute and relative areas which the author describes.

Apart altogether from Prof. Exner's deductions, one thing clearly brought out by the facts is the comparative impotence of the fortuitous experiments of disease as regards the determination with any degree of accuracy of the exact position and limits of any centre whatever. Prof. Exner has a deservedly high reputation as a physiologist, but the manner in which he has handled the facts of disease as set forth in this work is not one on which he can be congratulated.

In his selection of instances he has excluded, without assigning valid reasons, many cases of the utmost importance; and he has included, as instances of localised cortical disease, a large number of cerebral tumours, which by the general consent of pathologists, are excluded, owing to the indirect effect which tumours exert on other parts—effects which can never be estimated with any degree of certainty. In his meagre "sammlung" of 168 instances he has included over thirty cases of tumour, thereby introducing such a large percentage error as to vitiate the whole of his deductions however accurately they may be drawn from his premises. Causal relationship is too readily assumed when none is proved. Mere frequency of occurrence, on which alone he founds his peculiar notion of relative centres, by no means justifies the assumption of causal connection. These so-called relative areas are seen to be capable of destruction without discoverable symptoms, and the same region seems to play many parts, being indifferently a centre for the leg, or the arm, or the face, speech, sight, and so forth. Our author's arguments in favour of his relative centres are in reality not more cogent than would be the inference that because injuries of the foot are frequently associated with disturbance of the circulation, therefore the foot is a relative centre of the circulation, whatever that may mean. If Prof. Exner's localisation of relative centres had any foundation in fact, it would be nothing short of a *reductio ad absurdum* of the whole doctrine of localisation. It is a marvel how a believer in localisation, as Prof. Exner declares himself, can see no incongruity or inconsistency in admitting that the absolute centre for the leg may also be a relative centre of vision. A consistent advocate of localisation might as well admit that the leg may frequently, relatively, or in some way or other be used as an organ of vision.

Among other strange things in this book is the kind of evidence on which our author seeks to establish differences between the hemispheres as to the extent and relation of the sensory and motor centres. In one of his figures of the left hemisphere there is an area in the occipital lobe so coloured as to indicate the position of an absolute centre for the arm, meaning that lesion of this area causes paralysis of the arm in 100 per cent. of the cases. On referring to the evidence we find that the 100 per cent. means only *one* case, a case, moreover, in which there was profound impairment of all the cerebral functions, and extensive lesion elsewhere of the left hemisphere, invading also what is generally recognised as the motor area proper. It is true that in his remarks on this case our author doubts its conclusiveness as regards the arm centre; but inasmuch as his instances give him a case of lesion of the same region in the right hemisphere without any symptoms whatever, he considers it beyond all doubt that this area has a more intimate relation with the upper extremity in the left hemisphere than in the right. It would be difficult to believe that this was written seriously, were it not that a similar style of reasoning is so prevalent throughout the book. Though Prof. Exner advocates the localisation of function in the cerebral hemispheres, the support he gives it is of the most equivocal description.

DAVID FERRIER

THE ROD IN INDIA

The Rod in India. Being Hints how to obtain Sport, with Remarks on the Natural History of Fish, their Culture and Value, and Illustrations of Fish and Tackle. By H. S. Thomas, F.L.S., of the Madras Civil Service. Second Edition. (London: Hamilton, Adams, and Co., 1881.)

THIS is a very much enlarged edition of a very excellent and pleasant book, the first edition of which appeared not quite eight years ago. The author asserts that there is as good fishing, in the angler's sense, of course, of this word, to be had in India as in England; and to prove it we have this goodly royal octavo volume, of over 400 pages and 25 plates. Now, though the fishing is good, it soon becomes apparent that it is something quite peculiar; for though our author himself knew thoroughly well how to "circumvent" a trout in England, and had often done successful battle with the lordly salmon in more northern climes, yet at first he could make nothing of the Mahseer in India, and lost a frightful lot of time in learning the manners and the customs of this Oriental gentleman. The reader of this volume should not cer-

tainly be in such a plight, for he will find in it the minutest instructions for his guidance, and there seems not a *trait* in the character of this and the other freshwater fishes to be ordinarily met with in India that has not been scanned and studied by its author with the intent of beguiling these fishes to their own destruction.

Of the fish to be caught in Indian waters the best is the Mahseer (*Barbus tor*). It is the best from the sportsman's point of view, as it gives him most to do; for who that is a sportsman cares to haul up a dead pike on a night-line? and who that is a sportsman but must care for a fish that can attack as follows?—

"The Mahseer has a greater means than our salmon of putting on steam, and has the habit of always putting it on at once, energetically and unsparingly. His first rush is a mighty one, no doubt; that once made, his strength is, in comparison with the northern fish, comparatively soon exhausted. Other rushes he will make, but his first is the dangerous one; then it is that the final issue of the campaign is practically decided. Be one too many for him then, and you may be grimly satisfied that all else he can do will not avail him; you may count on making him your own. Then it is that you must wait upon him diligently. If you have not got all free, the connection between you and your new friend will be severed within a moment of your making each other's acquaintance. If you should have carelessly allowed the line to have got a turn around the tip of your rod, or have let any slack near the hand become kinked ever so little, or twisted over the butt or hitched in the reel or a button, then it is that not one moment's law is given you for the readjustment of such little matters. There is one violent tug, and an immediate smash:

"'The waters wild go o'er your child,
And you are left lamenting.'

Reader, it takes an eye and a hand, and tact and readiness of mind, as well as a rod and a line and a fly, to catch a salmon; but it takes all these, and something more, to catch a Mahseer."

Although it is well known that a fisherman does not catch his fish for the pleasure of eating them—this being quite a secondary matter—still it is fair towards the Mahseer to mention that when in good condition they are excellent, so rich that one needs no condiment with them, so well flavoured as in this respect to occupy a rank between a salmon and a trout. The best size for flavour is between six and seven pounds; but they are good eating when from two to ten pounds in weight; under the former size they are too bony, over the latter too oily.

The chapter on the natural history of this fish is one of the most interesting in the volume, and it is scarcely necessary to add that there are minute details of how to "circumvent" him, of how to spin for him, and of how to tempt him with a fly, and of how, when, and where to fish for him. When we add that over one quarter of the volume is taken up with this fish, it will be evident at once that he ranks as a lord among the freshwater fishes of India; but we have full details also of the Carnatic Carp (*Barbus carnaticus*), a nearly allied species to the Mahseer, running to twenty-five pounds in weight, taking a fly, having a fancy for a No. 5 or 6 Limerick, and giving good sport.

There are also excellent chapters on many much smaller fishes than these—fishes for light rods, and giving very enjoyable sport; several, like the Black Spot, being dwellers in ponds.

Some information is also given as to the attempts made to stock ponds in India, and there is a very full list given of fishing localities. The lithographs which accompany the volume are very good, and several of them are coloured. To the sportsmen of India this work will be quite indispensable and quite a boon, and further, to all interested in the resources of an Empire presided over by our Queen, the volume will afford an insight into the importance of its freshwater fishes that they will find, we believe, nowhere else.

OUR BOOK SHELF

Book of the Black Bass: comprising its Complete Scientific and Life History; together with a Practical Treatise on Angling and Fly-Fishing, and a Full Description of Tools, Tackle, and Implements. By James A. Henshall, M.D. Illustrated. (Cincinnati: Robert Clarke and Co., 1881.)

THE author in this volume endeavours, and we think succeeds, in giving to the Black Bass its proper place among the freshwater game fishes of North America; and undoubtedly the reader will find himself taking an interest in this fish as he reads this enthusiastic account about it. No doubt the first and second chapters will be most tedious reading, and yet they are full of interest as showing how tangled may become the scientific nomenclature even of a well-known fish. As the sum and substance of these chapters we find the two species of the genus Micropterus, standing, the one as *M. dolomieu*, and the other as *M. salmoides*, and it is of these two respectively—the small-mouthed Black Bass and the large-mouthed Black Bass—that the author writes. Both species are very active, muscular, and voracious, with hard and tough mouths, are very bold in biting, and when hooked exhibit gameness and endurance second to no other fish. Both give off the characteristic musky odour when caught. They generally inhabit the same waters. These Black Bass are wholly unknown in the Old World, except where quite recently introduced. Their original habitat is remarkable for its extent, for with the exception of the New England States and the Atlantic seaboard of the Middle States, it comprises the whole of the United States east of the Rocky Mountains, Ontario, and, last, Mexico. Of late years this distribution has been greatly extended. These fish are very prolific, and rapid growers where food is plentiful. In northern waters six to eight pounds is about the limit of their weight, but in Florida they are sometimes met with up to twelve and fourteen pounds. They have been several times imported into England, and we believe that those brought over in 1879 at the expense of the Marquis of Exeter have succeeded well. The fisherman who reads the latter portion of this volume will find many pleasant anecdotes and stories in connection with the gentle art, and should he happen to frequent those waters where the Black Bass are to be found, he will get many a precious wrinkle which he might have otherwise not known. The author's parting injunction is, "Always kill your fish as soon as taken from the water, and *ever* be satisfied with a moderate creel. By so doing your angling days will be happy and your sleep undisturbed, and you and I and the fish we may catch can say—

"'The lines are fallen to us in pleasant places.'"

An Introduction to Determinants, with numerous Examples. By William Thomson, M.A., B.Sc. (Edinburgh: Jas. Thin, 1882.)

THIS text-book is very accurately described by its title. It belongs to a class of which many examples have appeared on the continent for use in the secondary

schools, and of which the object is to give the more common properties of determinants, illustrate the said properties copiously with examples of the second, third, and fourth orders, and give additional examples of the same kind for practice. The object is here on the whole well attained, there being more examples for the pupil than is usual. For a "beginner's text-book," however, it is unquestionably long-drawn-out and expensive. A book (*e.g.* Dölp's, Bartl's, &c.) with very much more matter and, to say the least, as good in quality, would be got in Germany for two shillings, and this costs five. The object of the author "to render an interesting and beautiful branch of mathematical analysis more accessible to junior students" is thus somewhat frustrated at the outset.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A Glimpse through the Corridors of Time

THE eloquent and exceedingly interesting lecture by Prof. Ball, F.R.S., under the above title, reported in your journal, has brought to my mind a short, far too much forgotten paper by Immanuel Kant. With your permission I will give a few extracts from this paper, which cannot but be interesting to many of your readers. Kant became subsequently very celebrated in a sphere of human knowledge usually considered far removed from natural science, in consequence of which his papers relating to this science are now almost universally overlooked. Nevertheless some of them contain extraordinary glimpses of truth a century or more in advance of this time, glimpses possible only to genius.

The paper to which I wish more particularly to draw attention was published in 1754, when Kant was thirty years of age. It will be found in the collected works edited by F. U. Schubert and K. Rosenkranz (Leipzig, Leopold Voss, 1839, vol. vi. p. 4). The paper relates to the question whether the length of day has altered, and through what cause. In this paper Kant states: "If the earth were a perfectly solid mass, without any liquid, the attractions of the sun and moon would not alter the rate of rotation round the axis. . . . If, however, the mass of a planet includes a considerable amount of liquid, the united attractions of the sun and moon, by moving this liquid, impress upon the earth a part of the vibrations thus produced. The earth is in this condition." He then goes on to state that the moon produces the greatest effect, and, the tide running round the earth in a direction opposed to that of rotation, "we have here a cause, on which we can count with certainty, incessantly reducing this rotation by as much as it may be capable of." A little further on he says: "When the earth steadily draws nearer and nearer to the end of its rotation, this period of change will be completed when its surface is, relatively to the moon, at rest; *i.e.* when it rotates round its axis in the same time in which the moon revolves round it, and will, consequently, always show the same face to the moon. . . . If the earth were entirely fluid the attraction of the moon would very soon reduce its rotation to this minimum. Herein we at once see a cause why the moon always shows the same face to the earth. . . . From this we may conclude with certainty that when the moon was originally formed, and still fluid, the attraction of the earth must, in the manner above described have reduced the speed of rotation, which then in all probability was greater, to the present measured limit." I have given only a few short abstracts, and I have no doubt that mathematicians may find many faults in the paper, but it is nevertheless clear that Kant had recognised the influence of tidal action, both on the earth and on the moon, and has given a glimpse through the corridors of time a century earlier than any of the authorities mentioned by Prof. Ball.

After Kant it was, I believe, R. T. Mayer, of Heilbron, who, long before Prof. Helmholtz drew attention to the influence exerted by the tidal wave on the rotation of the earth.

Westminster Hospital, December 5, 1881 A. DUPRÉ

Dante and the Southern Cross

I HAD supposed the query—in reply to which I ventured to offer the very brief note which was printed in NATURE (vol. xxv. p. 173)—to have proceeded from some English reader, unacquainted with the various solutions of the difficulty involved in the question, which have been suggested, and who might have been satisfied with a reference to such a discussion of the matter as that in the "Cosmos," by a critic in whom were united all the needful qualifications to a degree which can hardly be looked for elsewhere.

Dr. Wilks appears to have written with a similar impression in referring the querist to the commentary of the late distinguished Dantophilist, Dr. H. C. Barlow, whose fervid belief in the extent of Dante's knowledge ("ottimo Astronomo, summo Teologo") could not be exceeded by the most ardent patriotism, and was never qualified by the judicious reservation which Signor N. Perini admits. What I venture to add, refers to the notes which have appeared, rather than the original query as I understood it.

For a solution of the apparent paradox in Humboldt's retaining the old view of the sense of "prima gente" while accepting —not Galle's "opinion," but—the result of his computations as to the visibility of the stars of the Southern Cross to the earlier inhabitants of Europe, I would refer Signor N. Perini to the earlier and much fuller development of Humboldt's views, contained in the last twenty pages or so of vol. iv. of the *Examen Critique de l'Histoire de la Geographie Moderne*, where, at the same time, will be found a great deal of valuable and suggestive information relative to the Arabian celestial globe theory, and also to the probability (the words "non viste mai . . ." notwithstanding) of Dante having derived some knowledge of the constellations of the southern hemisphere from the description of "Les voyageurs pisans ou vénitiens qui visitaient l'Egypte, l'Arabie et la Perse." But I would at the same time urge that the whole of what is said in the "Kosmos" on the subject of the Southern Cross is not intended to be applied to the Dante question, but to the larger one of the progress of oceanic discovery, and that it was in connection with this larger topic that Humboldt availed himself of Dr. Galle's computations. Dr. Barlow appears to have been misled by failing to notice this distinction in his enthusiastic letter to the *Athenæum* (September 1860) of which the article quoted by Dr. Wilks from the volume of "Contributions to the Study of the Divina Commedia" is a condensation.

Count St. Roberts's essay, to which Signor N. Perini refers, is probably little known, and not easily obtained, in England; but we may conjecture that its object was to argue against the supposition of the element of ecclesiastical mysticism—hateful to modern Italian liberalism—as entering into the Divina Commedia and affecting its imagery and modelling. If the essay had thrown any new light on the subject of the query, we may conclude Signor N. Perini would have imparted it to us. However, I believe that everything that can be found to throw light on this interesting question has been adduced and weighed with the dispassionate calmness of a master mind, as it is set forth with candour and perspicuity in the exhaustive discussions to which I have referred. In conclusion may I remark on the importance, in such correspondence as we have been engaged in, of quoting the original words of an author—with or without translation, as may be thought proper. In the quotation, as from "Cosmos," by Dr. Barlow, given by Dr. Wilks and the passage is re-quoted by Signor Perini—nonsense is made of a sentence by "da" being rendered "since," instead of "whereas." In the same translation "mit vieler Orientalischen Reisenden aus Pisa" is improved into "with many *learned* Oriental travellers of Pisa." Such changes might sensibly affect any argument founded on the passages. For the same reason I would have preferred heading this correspondence "Dante and the quattro stelle." J. J. WALKER

University Hall, December 31

A Pet Baboon

I KNOW not if the inclosed account, written by a friend of mine now resident at Zanzibar, for whose accuracy and truthfulness I can answer, is worthy of a place in your columns.

JULIA WEDGWOOD

"You ask after my quaint little pet baboon, and I really must give you the history of her end. She grew and she grew till

she got to be half as tall as I am, and then, sad to relate, with advancing age her temper did not improve; I am afraid if I spoke the truth I should have to describe it as savage. She became a perfect terror to many people, and she even attacked me once or twice. She was playful to the last when I had her alone, and often resumed many of her old quaint caressing ways that were indescribably fascinating from their childlikeness. But the funny thing was, that if the Bishop was near she would immediately turn upon me and scratch and bite me, and he had only to go out of sight for her good temper to return. At last, however, I felt she was becoming a nuisance to other people, by her habit of grabbing at everybody that passed, and her savage gesticulations; so, seeing also how she longed to exercise those active wiry little limbs of hers—inventing all sorts of ludicrous games and gymnastics—I made up my mind to let her loose. There is a charming little island not far from the shore, which we thought would be just the place Judy would revel in. Mr. —— and Miss ——, and a number of our little boys, escorted her there. She came down to the shore to watch them off, and gave one cry of dismay at being deserted; but we hope that the sweets of liberty have more than consoled her for the loss of society. I missed the creature dreadfully at first. She was a constant amusement and interest with her quaint ways, and even her naughty tempers were ludicrous. Really if Mr. Buckland had been alive I think I should have sent her to him. I think he would have appreciated her intelligence and love of a romp, and she would never have been savage with him. She never once attempted to bite our Bishop; she always preferred him to any one else, and was always affectionate with him. I want very much to know whether other people have noticed that these baboons really laugh; I have heard somewhere, I am sure, that the power of laughter is the distinction between man and animals. But Judy certainly used to laugh—not at a joke I confess; and nothing made her so savage as being laughed at. But when she romped with me she used to open her mouth and show all her white teeth, and regularly laugh like a child, especially when she was tickled. I shouldn't have parted with her if I had been living alone, but living with others, as one does here, it did not seem fair to keep a creature that really did frighten some of the household."

"Tanganyika Shells"

UNDER the above heading a paragraph appeared in NATURE, vol. xxv. p. 101, in which Mr. C. A. White, of Washington, states that certain species described by me in the *Proceedings* of the Zoological Society, 1881, pp. 558-560, from the great African Lake Tanganyika, "are without doubt, generically identical with the *Pyrgulifera humerosa* of Meek," a fossil form from the Bear River Tertiary of North America. Mr. W. H. Dall, of the Smithsonian Institution, had previously, in a letter to me, dated October 24, expressed a similar opinion. I have been unable to procure for examination and comparison a specimen of the North American shell, and am consequently compelled to arrive at a conclusion from a study of Mr. Meek's figure and description in the report upon the "United States Geological Exploration of the Fortieth Parallel," vol. iv., pp. 176-178, woodcut 6, and plate 17, figs. 19-19*a*. As a result I find it decidedly unadvisable at present to locate the two forms in question in the same genus. I admit that in regard to general outline and character of "sculpture" there is no distinction of any importance. However, when the aperture (which in univalve shells most frequently exhibits the main generic characters) is closely scrutinised, features present themselves which incline me, until actual comparison is possible, to hold these two types generically distinct. The outer lip of *Pyrgulifera* is said to be "subsinuous at the termination of the shoulder of the body volution above," and the basal margin of the aperture is described as "faintly sinuous." On the contrary, in *Paramelania* no trace of the latter character is present, and the upper extremity of the labrum where it joins the volution, instead of being "*subsinuous*," is actually *prominent*. But another equally important distinction is the prolongation of the body-whorl below the aperture, together forming a more or less basal effusion. Independent of these actual differences, we must take into consideration certain probabilities and improbabilities. In the first place the difference in geographical position militates to some extent against the identity of these two forms. Then the vast lapse of ages surely must have evolved some differences in the animals as indicated by the dissimilar apertures, and again the operculum of *Paramelania* is very peculiar, and who shall say that this appendage was of a like nature in the Bear River shell. In conclusion, I should observe that the African form was considered of sub-generic rank by me, and not as a distinct genus, as stated by Mr. White.

EDGAR A. SMITH

The Growth of Trees

JUST fifty years ago I was at school in Salisbury. I have only visited it once since until last week, when I had the unique pleasure of rambling over the old but familiar haunts, of course including Old Sarum. On mounting the outer ring of the well-known mound from the Stratford side, a beech tree in the bottom of the ditch reminded me that it was just there our usher carved with his knife on such a tree "Tempus Fugit." On going down to look for the motto, I only found unreadable abrasions on the bark, but on the north side of the same tree "1817" was distinctly engraved. On examining a tree near, I found on the bark "Carpe Diem, 1831." This recalled to my memory the fact that our usher's "Tempus Fugit" was suggested by some such motto carved by the usher of another school. Is it worth recording that this carving on the bark of a beech tree is quite legible after an interval of fifty years, while the date "1817" on another is also probably genuine? If so, perhaps it is worth noticing that both legible carvings are on a north aspect not reached by the sun, while the lost motto "Tempus Fugit" would be exposed to the sun with an easterly aspect.

Barnstaple, January 2 W. SYMONS

INDIAN FOSSILS.—Mr. Richard Lydekker, of the Geological Survey of India, asks if any of our readers can give him information as to the whereabouts in England of collections of fossil bones from the Siwaliks of India. He is aware (beside the British Museum collection) of collections at Ludlow, Cambridge, and Edinburgh, but he believes there are others in the country. A large collection was sent home some years ago by a Major Hay, the destination of which is unknown to him. Mr. Lydekker is now engaged in working at Siwalik fossils, and as he intends spending some months in England next summer, he wishes to look up all the collections then.

OUR ASTRONOMICAL COLUMN

COMET 1881 *b*.—Notwithstanding some statements to the contrary, the orbit of this comet when the later observations are brought to bear upon it, is sensibly different from a parabola, and from two independent investigations, the first by MM. Dunér and Engström, the second by M. Bossert (from eight normal places, based upon 423 observations), the period results about 2955 years. An observation at Marseilles on October 24 gave at 9h. 39m. 4s. mean time, R.A. 18h. 44m. 58·12s., N.P.D. 20° 24′ 23″·2, corrected for parallax.

The following positions are given by Dr. Dunér:—

At 12h. Berlin M.T.

		R.A. h. m. s.		Decl. N. ° ′		Distance from Earth.
January 10	...	22 58 11	...	57 28·3	...	3·118
12	...	23 3 4	...	57 15·5		
14	...	— 7 53	...	57 3·3	...	3·195
16	...	— 12 39	...	56 51·5		
18	...	— 17 22	...	56 40·3	...	3·274
20	...	— 22 1	...	56 29·5		
22	...	23 26 38	...	56 19·2	...	3·354

The student of this branch of astronomy will be aware that comets have been followed to greater distances; the extraordinary comet of 1729, which never approached the earth, indeed could not approach her, within three times the earth's mean distance from the sun, and yet was visible with small telescopes, still affords a unique case, it must have been a body of an altogether exceptional character.

THE MINOR PLANETS IN 1882.—The supplement to the *Berliner Astronomisches Jahrbuch* for 1883, containing ephemerides of the small planets for 1882 has been circulated in advance of the publication of the volume as usual for some years past. Of the two hundred and twenty members of the group detected up to the present time, we find approximate places for every twentieth day of 217, and accurate opposition ephemerides of 41. The approximate ephemerides include No. 220. Three only of the planets approach the earth at opposition, within the earth's mean distance from the sun, viz. No. 12, *Victoria*, in

August, distance 0·891; No. 80, *Sappho*, in September, distance 0·847; and No. 27, *Euterpe*, in December, distance 0·980. No. 157, *Dejanira*, comes into opposition and aphelion about the same time, and the magnitude descends to 15·7. The last of the minors discovered is in opposition in December, mag. 14·6, but No. 216, also a recent discovery, is as bright as 8·4 at opposition on October 7. There is perhaps not much hope of recovering *Medusa* (which from the best orbit obtainable from the short course of observation in 1879 would appear to have the least mean distance amongst the small planets) in the present year, the magnitude being only 13·5, and the computed places necessarily liable to considerable error. Nos. 205, 207, 208, 210, 212, 216, 218, 219, and 220 are still without names.

MR. W. R. BIRT.—Mr. Birt, so well known in connection with lunar work, died at Leytonstone on December 14 in his seventy-eighth year. He had occupied himself some fifty years since with the variable stars, and announced in 1831 the variability of α Cassiopeiæ, a difficult case, for the fluctuation in its light would appear not to exceed a half-magnitude, and indeed has been doubted by no less an authority than Prof. Julius Schmidt. Sir John Herschel, however, supported Mr. Birt's conclusion, and we were once shown by the late Prof. Heis a series of curves exhibiting the results of several years' observations, which indicated sensible though very irregular variability. Much of Mr. Birt's lunar work was undertaken under the auspices of a Committee of the British Association, and his maps of various parts of the moon's surface, extending to great detail, are well known.

M. ALFRED GAUTIER.—In the death of M. Alfred Gautier, at Geneva, on November 30, at the age of eighty-eight years, as already announced, the Royal Astronomical Society have lost the oldest Associate upon their list; he died in full possession of his faculties after a very short illness. M. Gautier was elected into the above Society in January, 1822, or two years after its formation. M. Plantamour of Geneva now heads the list of Associates.

THE SMOKE ABATEMENT EXHIBITION

THIS Exhibition originated, as explained in the introduction to the Catalogue, in the action of the Committee of the National Health Society, with whom the Kyrle Society afterwards joined in appointing a Joint Committee to consider how action could be taken which should tend to the abatement of the smoke produced in the metropolis. In the words of this introduction, "The first proceeding of the Committee was to communicate with colliery owners and manufacturers of heating apparatus as to the means available for the reduction of smoke, and next with the metropolitan parochial authorities and public bodies, directing their attention to the serious and increasing evil, and asking their co-operation in abating it." Public meetings were held at the Mansion House and other places in different parts of London; and the public interest in the subject appearing to be sufficient to justify such an experiment, the Committee determined to hold an exhibition of appliances for the reduction of smoke both in manufacturing and domestic fires.

The idea entertained by the promoters of the Exhibition has been that, in order to effect a reduction in the quantity of smoke poured out of chimneys of different kinds in large towns, it was first necessary to convince people that appliances exist which will tend to this result, and it was therefore determined to invite an exhibition of smokeless fuels, and apparatus for burning them, as well as of appliances for lessening the amount of smoke given off by bituminous coal. The call has been very readily responded to, and the catalogue shows a list of over 230 exhibitors.

Tests are being made by experts of the performances of the different apparatus, which, in the case of the domestic grates, &c., are carried out in specially constructed rooms; the fumes passing up the chimneys being carefully examined to determine the quantities of carbon (other than carbonic acid) and other unconsumed matter passing away from the fire; the consumption of fuel and the temperatures maintained being also carefully noted. A jury has been appointed to award prizes, medals, &c. to those appliances which they consider best adapted to fulfil the purposes in view.

The Exhibition is naturally divided into two great divisions: appliances for trade purposes, and those for domestic purposes. In the first division the economic use of gas instead of solid fuel is illustrated in a small kiln for burning pottery and glass, and its use, instead of steam, is shown in several different kinds of gas-engines. The means of producing steam, however, occupies the principal place in this division. Several mechanical stokers and other appliances for firing boilers, so as to produce no visible smoke, are shown, and those which are at work demonstrate that—at least after steam has once been got up—it is easy to raise any quantity of steam without the production of smoke at the top of the chimney. Moreover, as these appliances are stated, on apparently good authority, to effect an economy in the expense of raising steam, it is to be hoped that their adoption is rapidly becoming general.

It is with the second division, however, that most individuals are more particularly interested, and it is from fires of this kind that the bulk of the smoke is produced, at all events in the west end of London.

Domestic fires, again, may be divided into two classes, those for cooking and those for warming rooms. It is with the latter that we propose to deal in this article. And first we will consider what it is that we want in our living rooms. We are strongly of the same opinion as Sir F. Bramwell, that we must have an "open, pokeable, companionable fire."

We believe that the value of an open fire for warming living rooms cannot be too strongly insisted on; Dr. C. W. Siemens has lately pointed out why a room in which the air is comparatively cool, and the walls, furniture, &c., are warmed by rays from the fire, as is the case when an open fire is used, is so much more pleasant and healthy than one in which the air is warmed by contact with hot surfaces of the stove or heating apparatus, and the walls, furniture, &c., are at a lower temperature, and we believe it is to the use of open fireplaces that the general freshness of complexion of the inhabitants of these islands, and the absence of the use of spectacles among the young, are in a very large measure to be attributed.

One disadvantage in open fires, which has been much dwelt upon—the waste of fuel—is we believe considerably exaggerated. Doubtless a small proportion of the coal used in an open fire-place would be sufficient to maintain the temperature of a room if a close stove were used. But is the rest so entirely wasted as some would have us believe? The greater part of the heat, as they say, "goes up the chimney." Is it therefore wasted? We think not. It performs work in ventilating the room, and it is at least doubtful whether in an ordinary dwelling room the same quantity of vitiated air could be removed (and therefore the same quantity of fresh air be introduced) as cheaply and conveniently by any other means; at all events, the so-called "waste heat" could not be made use of to any large extent as radiant heat, and open grates are shown in the exhibition in which a part is utilised in warming air for admission to the room, or heating water-pipes, &c.

The problem of how to have an open fire without smoke, or with considerably less smoke than we have at present, is one towards the solution of which we hope this exhibition will give valuable assistance. Fires are shown in which gas, coke, these two together, anthracite, or Welsh coal, and bituminous coal, respectively are the fuel. Several different kinds, both of gas stoves and open gas fires are shown. There seems to be no novelty in any of them, and we believe that they are generally so well known as to need no description here; they have the merit of being extremely handy and cleanly; they are not

"pokeable" nor very "companionable," and we are afraid that the very unpleasant fumes of burnt gas—caused, we suppose, by so many of the gas fires shown not being provided with flues—which pervade this portion of the exhibition when the gas apparatus is shown, must prejudice visitors very much against the use of these very valuable appliances.

Dr. Siemens' coke and gas fire, which has been so recently described in these columns, is shown by several exhibitors. It is necessarily free from visible smoke, and almost so from dirt and dust, and it is very manageable; that is to say, by altering the supply of gas the heat may be easily and quickly regulated. How far it is free from the noxious fumes which usually seem to accompany the combustion of coke or smokeless coal in a room cannot be judged in the exhibition.

The same remark applies to the many grates shown for burning anthracite and smokeless coal. Many of these look very nice; a bright, hot fire is obtained which almost comes up to Sir F. Bramwell's standard. It seems to us, however, that anthracite fires are not very manageable; the fire must burn at one rate, and the fuel must be supplied accordingly; you cannot quickly get up a hotter fire by the use of a poker, as is so easy with bituminous coal, nor can you so easily reduce the fierceness of the fire as can be done with so many grates in which bituminous coal is burnt. The absence of smoke is, however, a very great advantage, and unless this can be attained, or nearly so, with bituminous coal, we ought to be prepared to give up the luxury of its use.

There are two methods by which it appears possible to reduce very considerably, if not to prevent entirely, the production of smoke in domestic grates. One is to supply the coal to the fire in such a way that the smoke and gases escaping from the portion last supplied may pass through the live coals and so be consumed; the other is to introduce a draught of hot air at the top of the fire, there to meet and consume the smoke and gases given off by the newly-supplied coal.

Dr. Arnott's stove is a type of the first method. In it the coal for the day's use is put into a box underneath the grate, which latter has no bottom; by means of a lever the bottom of the box is raised, and fresh coal pushed into the fire as required. There is thus no escape for the gases given off by the fresh coal but through the hot part of the fire. These stoves, however, have never come into very common use. We believe that they are not found to be pleasant in a room, and that the reason of this is that although little or no smoke is given off, there is not sufficient air admitted to the fire to burn the carbonic oxide produced, the grate being closed at the bottom, sides, and back, and the front being narrow. No stove of exactly this description is shown in the exhibition, though there are several in which the principle for getting rid of the smoke is adopted. Messrs. Brown and Green, of Luton, Bedfordshire, show a register stove for bituminous coal (and a kitchen range on the same principle), in which the coal is supplied to the fire by a kind of trough or shallow hopper placed in front of the bottom bars, from which the coal can be pushed into the fire, to facilitate which operation the bottom of the grate is made to slope upwards towards the back. Mr. Engert places a box for the fuel at the back of the grate. This box has a sliding back worked by a screw underneath, by which means the fuel is pushed forward into the fire as required. He thus secures a wide front for his fire, and less depth of live coal than in Dr. Arnott's stove. By means of a kind of baffle plate hung at the back of the grate the gases issuing from the coal-box are deflected into the fire instead of going up the chimney. The coal-box can be recharged if necessary without actually putting out the fire. It appears possible to adopt this arrangement to an existing grate of ordinary form at comparatively small expense.

Messrs. Martin and Co. seek to attain the same object by having movable cheeks to the grate, which work horizontally inwards by levers. The coal being put on at the sides is gradually pushed in by this means towards the more active part of the fire. The back plate of the grate has a space behind, and is perforated in the centre so that heated air is thus admitted at the centre of the back of the fire to assist in the combustion.

Thompson's patent consists in having the front of the grate made so as to slide upwards a few inches. The bottom of the grate consists of a plate of iron and is fixed. For the purpose of putting on fresh coals a tool is used consisting of a sheet of iron of the same shape and size as the bottom of the grate, hinged to a rod somewhat like an ordinary poker at a distance from its end equal to the height from the hearthstone to which the front of the grate rises. The iron plate being pushed in between the coals and the bottom of the grate with the rod in an inclined position, the handle of the latter is pushed forwards, the whole body of the fire and the front bars are thus lifted a few inches, and the fresh coal is put in between the two plates; the implement being withdrawn, the front of the grate falls again to its proper place, and the live coals come in immediate contact with the fresh coal underneath it. The back of the grate is perforated, so as to admit heated air to the fire. This arrangement could probably be adapted to many existing grates, without very great expense.

Saxon Snell's patent consists of a cylindrical grate mounted on a very strong horizontal pivot at the back, and in the line of its axis. At opposite sides of the perpihery are two grated doors which are hinged to the back edge of the grate; the uppermost one is opened, and lies back against the chimney-back. When fresh coal has been put on, the upper door is shut and fastened, and the grate turned half round, so as to bring the other door to the top, and the live coal above the fresh coal. We believe that the combustion in this grate would be improved by some holes in the back through which heated air might be admitted near the top of the fire, and these could easily be made.

The grate shown by E. R. Hollands, of Newington Green, is rather more complicated than some of those which we have described; but its performance appears to be good. A movable set of bars fit in between the fixed bottom bars of the grate; and the lower part of the front is made to open forwards and downwards. A neatly-devised motion worked by a lever at the side of the fire-place raises the movable bottom bars, and with them the fire, and opens the lower part of the front, the fresh coal being then placed between the two sets of bars, the return of the lever to its place causes the front of the grate to shut and the movable bottom bars first to recede through the back, and then, having fallen below the level of the fixed bars, to come forward and up again into their original place. The back of this grate is hollow and is pierced with small holes at about the level of the top of the fire. The combustion effected by the hot air passing through these holes is clearly visible.

In the slow combustion grate of Fredk. Edwards and Son, which is shown in action, the "Arnott" principle is made use of, but instead of the bottom being movable, a counterbalanced shutter works vertically in front of the grate, which is very deep. The latter being filled and the fire lighted from the top, the shutter is adjusted from time to time, so as to obtain the requisite amount of fire, by exposing more or less of the front of the grate.

Messrs. Musgrave and Co., of Belfast, besides several of their well-known "slow-combustion" stoves, show a fire-place which they call the "Ulster." In this the coal is fed into the back of the fire from a hopper placed behind the chimney-back, in which is a close-fitting door for closing the opening through which the hopper is filled. The coal is pushed forward into the fire by an arrange-

ment worked by a lever at the side of the grate. The coal is thus coked before it comes into the fire, the only escape for the gases being through the glowing coals. Somewhat similar in some respects to this is the "Wonderful" grate of Archibald Smith and Stevens. In this the fireplace is closed by an iron plate, in which are three rectangular openings one above the other. To the lowest, which is about the floor-level, the grate is fitted; this, made of a basket shape, can be mounted on a pivot in the plane of the plate, so that more or less of the grate may project into the room. Between the top hole in the plate and the upper half of the bottom hole is a flat-sided tube, which curves backwards into the fireplace. This is the hopper for the fuel; it is shut at the top by a close-fitting door, and the curved shape causes the fuel to descend easily into the fire. The centre opening of the plate is provided with a register door, and in some instances is covered with a hood. The arrangement of the hopper causes the gases evolved by the fresh coal to pass through more or less of the live coal before they can escape, and by closing the centre opening the whole draught is made to go down through the lower half of the bottom opening, causing a rapid combustion. Four of these grates are shown in action, with different sorts of fuel. They seem to require little or no attention for hours together, as the feeding arrangement appears to act well.

A grate of the pattern which has been in use in barracks for the last two or three and twenty years is exhibited. This grate was devised by Capt. Douglas Galton. It consists of a cast-iron stove, entirely open in front, which is fitted to the chimney opening, leaving a considerable space between the stove and the brickwork at the back. Into this space air is admitted from the outside of the building. From the top of the fireplace recess proceed two flues; one, the ordinary chimney-flue, receives the covered smoke pipe from the stove, the other delivers into the room through a lowered opening a little below the ceiling level, the air which has been warmed in the chamber behind the stove, the back of which has iron plates projecting from it, so as to increase the heating surface. The cast-iron stove is entirely lined with fire-brick, in the manner to be described, so that the air does not get unduly heated.

A little above the level of the fire the stove is gathered in towards the room so as to form a kind of baffle. The actual grate is formed as follows:—two fire lumps are placed on the hearthstone with a space between them of six inches or so, over which is a cast iron grid; the cheeks and back, all of fire-brick, rest on these first lumps; another lump of fire-brick of curved section underneath fits on the top of the back and cheeks, and underneath the gathered in part of the stove. Between the back fire-lump and the iron back is a space, and there is also a small opening between the back piece and the top piece, through which air heated at the back plays on the top of the fire and helps to consume the smoke. This stove is, we understand, found to be very economical in action, and is very highly spoken of in the work of the late General Morin on Heating and Ventilating. It will not, however, be tested in this Exhibition, as it is not shown in competition.

Messrs. Barnard and Bishop, of Norwich, have pushed the "baffle" principle still farther in their "glow" stove. Instead of coming only about half over the fire as in the Galton grate, the baffle consists of a fire-brick which projects nearly to the plane of the front bars of the grate, and slopes down slightly towards the front. The bottom of the grate, which slopes upwards, and the back which slopes backwards, are made of fire-brick in one piece, the front bars being the only ironwork about the grate. A flue which goes up behind the back opens to the fire just under the back edge of the baffle, the space under which and over the fire is thus converted into a combustion chamber in which the gases from the coals are burnt, and as these have to pass over the front of the baffle before going up the chimney the radiant heat from them comes into the room.

Several grates are shown by different makers, in which the combustion of the gases is accomplished with a down draught. But in these cases the radiant heat evolved in the process cannot come into the room directly, as it does in the case of the "glow," it is therefore lost in the case of a grate set in a fireplace unless it be utilised to heat air which is admitted to the room. A small open-fronted stove on this principle is shown by Mr. T. E. Parker, in which the combustion appears to be very perfect. The internal arrangement is too complicated to describe without a drawing, but the essential point is that the draught from the fire is led away at the back of the bottom of the grate into a flue lined with fire-brick, where it meets a draught of fresh air which has been warmed by contact with the underside of a ribbed plate which forms the bottom of the grate.

Several examples of grates with down draught and chambers for heating air to be admitted to the room are to be found in the exhibition, as well as some in which the heating chamber or flues are applied to grates with ordinary up-draught. The warm air inlets are usually placed close to the fire, which is, in our opinion, a mistake, as the general circulation of air in the room is not so much promoted by this arrangement as when the inlets are at some distance from the fire; there are, however, difficulties in so placing them in an ordinary living-room.

A stove of a peculiar, and we believe quite novel, construction is shown by Mr. James B. Petter. The recess of the fireplace is lined with white marble; in each jamb is a circular hole from which a pipe leads round to the chimney. The fire-box is mounted on legs with castors, so that it can easily be rolled in or out of the fireplace, and is provided with horizontal exit flue pipes at the sides which are connected with the openings in the jambs by sliding pieces. A vertical section of the fire-box from front to back is of open spiral or Nautilus form. The box is made of iron and lined with fire-brick from the lip to the top of the back, there being no bars either in the front or bottom. The coal is put on thinly at the lip, and gradually pushed back, as in stoking a steam-boiler. A rather sharp draught is produced over the red hot fuel towards the back, and the convolution of the box appears to form a kind of combustion chamber. It would seem that the difficulty of lighting the fire would be considerable, but it appears to work well.

We have endeavoured in this notice to give a slight sketch of such grates, &c., as present any salient features. We may have overlooked some which were deserving of notice, but we would earnestly recommend our readers to pay a visit to this very interesting exhibition, and to form their own opinion of the merits of the various apparatus shown.

We may mention that representatives have been accredited to the Exhibition by the Governments of Austria-Hungary, France, Prussia, Saxony, and the United States; and that the interest taken in it has encouraged the Committee to entertain the idea of holding an International Exhibition in about three years' time of such further developments of smoke-abating appliances as may be produced either in this or other countries during the interval.

THE CHEMISTRY OF THE PLANTÉ AND FAURE ACCUMULATORS

PART I.—*Local Action*

AMONG the important discoveries of late years, few have claimed so much attention, or have been so full of promise for practical use, as the accumulator of

Planté and its modifications. Our attention was very naturally directed to the chemical changes that take place in these batteries, especially as it appeared to us that there must be certain analogies between them and some actions which we had previously investigated. In the present communication we propose to treat merely of one point—that of local action, leaving the fuller discussion of the subject to some future occasion.

It is well known that metallic zinc will not decompose water even at 100° C., but we found that zinc, on which copper had been deposited in a spongy condition, was capable of splitting up the molecule even at the ordinary temperature, oxide of zinc being formed and hydrogen liberated. If placed in dilute sulphuric acid, it started a very violent chemical action, sulphate of zinc and hydrogen gas being the result. We termed the two metals thus conjoined, the *copper-zinc couple*, and this agent was fruitful in our hands in bringing about other chemical changes which neither metal singly would effect. Electricians will readily understand the nature of this agent, and will recognise in its effects only a magnified form of what we are all familiar with under the name of *local action*. Now the negative plate of a Planté secondary battery is a sheet of lead, upon which finely-divided peroxide of lead is distributed. It is well known that the electromotive force of lead and lead peroxide in dilute sulphuric acid is nearly three times that of zinc and copper in the same liquid. We were therefore induced to think that the plate must act in the same way as our copper-zinc couple. We found such to be the case. If a plate so prepared be immersed in pure water, the decomposition of the liquid manifests itself by the reduction of the puce-coloured peroxide to the yellow monoxide. There could be little doubt therefore that the lead peroxide couple, if we may call it so, would decompose sulphuric acid, with the production of sulphate of lead. This also was found to be the case.

As the destruction of peroxide of lead means so much diminution of the amount of electric energy, it became interesting to obtain some definite knowledge as to the rapidity or extent of this action.

When the peroxide of lead on the metal is very small in quantity, its transformation into the white sulphate goes on perceptibly to the eye, but when the coating is thicker, the time required is, as might be expected, too long for this kind of observation. In one experiment, following the procedure of Planté, we formed the peroxide on the plate by a series of seventeen charges and discharges, or reversals, each operation lasting twenty minutes, and the time was further broken up by seven periods of repose, averaging about twenty-four hours in length. After the last charge we watched the local action taking place, and found that the whole of the peroxide passed into white sulphate within seventeen hours. In another experiment the two plates formed according to Planté's method were immediately joined up with the galvanometer, and the deflection noted. They were then at once disconnected. After the repose of one hour they were joined up again, and another observation taken with the galvanometer. This was repeated several times, with the following results:—

Initial strength of current	100
After 1 hour's repose	97
,, 2 ,, ...	40
,, 4 ,, ...	14
,, 17 ,, ...	1·5

It results from this that during each of the long periods of repose recommended by Planté the peroxide on the lead plate is wholly, or almost wholly, destroyed by local action, with the formation of a proportionate amount of sulphate. But this is not, as it would seem at first sight, a useless procedure; for, in the next stage, the sulphate is reduced by electrolytic hydrogen, and, by a process which we hope to explain when discussing the complete history of the reaction, the amount of finely divided lead capable of being peroxidised is increased. That this is actually the case is shown by the following experiment. The peroxide formed on a lead plate by first charging was determined and called unity: it was allowed to remain in a state of repose for eighteen hours, charged a second time, the peroxide again determined, and so on:—

Separate periods of repose.	Charge.	Amount of peroxide
—	First	1·0
18 hours	Second	1·57
2 days	Third	1·71
4 ,, ...	Fourth	2·14
2 ,, ...	Fifth	2·43

In other trials, following the procedure of Faure, we employed plates in which the peroxide was formed by the reduction of a layer of red lead (containing 51 grains to one square inch of metallic surface) and subsequently completely peroxidising the spongy metal so produced. In one series of experiments we left the peroxidised plates to themselves for various periods and determined the amount of sulphate formed. This gave us the amount of peroxide consumed.

Experiment I.	after 2	hours	7·2	per cent.
,, II.	,, 3	,,	15·1	,,
,, III.	,, 4	,,	19·8	,,
,, IV.	,, 5	,,	30·0	,,
,, V.	,, 24	,,	36·3	,,
,, VI.	,, 7	days	58·3	,,
,, VII.	,, 11	,,	67·3	,,
,, VIII.	,, 12	,,	74·3	,,

The last experiment was tested with the galvanometer during its continuance, as in the case of the plate formed by Planté's method, with the following results:—

Initial strength of current	100
After 1 days' repose	92
,, 3 ,, ,, ...	79
,, 4 ,, ,, ...	34
,, 5 ,, ,, ...	24
,, 7 ,, ,, ...	11
,, 9 ,, ,, ...	8
,, 12 ,, ,, ...	1

It is evident from these observations that a lead-peroxide plate gradually loses its energy by local action, and that the rate varies according to the circumstances of its preparation.

Two difficulties will probably present themselves to any one on first grasping the idea of this local action:—1. Why should a lead plate covered with the peroxide and immersed in dilute sulphuric acid, run down so slowly that it requires many hours or even days before its energy is so seriously reduced as to impair its value for practical purposes? In the case of the copper zinc couple immersed in the same acid, though the difference of potential is not so great, a similar amount of chemical change would take place in a few minutes. 2. In a Planté or Faure battery the mass of peroxide which is in contact with the metallic lead plate expends its energy slowly. How comes it to pass that if the same mass of peroxide be brought into connection through the first lead plate with another lead plate at a distance, it expends its energy through the greater length of sulphuric acid in a tenth or a hundredth part of the time?

The answer to these two questions is doubtless to be found in the formation of the insoluble sulphate of lead, which clogs up the interstices of the peroxide and after a while forms an almost impermeable coating of high resistance between it and the first metallic plate.

The following conclusions seem warranted by the above observations:—

In the Planté or Faure battery local action necessarily takes place on the negative plate, with the production of sulphate of lead.

The formation of this sulphate of lead is absolutely

requisite in order that the charge should be retained for a sufficient time to be practically available.

The rapidity of loss during repose will depend upon the closeness of the sulphate of lead and perhaps upon other mechanical conditions. These are doubtless susceptible of great modifications. We do not know how far they are modified in practice, but it is conceivable that still greater improvements may yet be made in this direction.

J. H. GLADSTONE
ALFRED TRIBE

STEUDEL'S NOMENCLATOR

ALL working systematic botanists use Steudel's "Nomenclator botanicus seu Synonymia plantarum universalis" as an indispensable book of reference. It is an alphabetical list arranged under genera of published names of plants, giving their native countries and the authors who published their descriptions. Synonyms are as far as possible given under the species to which they belong. The second volume of Steudel's work was published in 1841, and it is probably not far wrong to assume that the existing mass of described plants has since doubled.

Mr. Darwin has with equal kindness and generosity expressed the wish to aid in some way the scientific work carried on at the Royal Gardens, Kew. The attempt has been made for many years to keep up in the herbarium there a copy of Steudel with manuscript additions, for the use of persons engaged in the study of any particular group of flowering plants. By reference to the Kew Steudel it is possible to ascertain to a large extent what has been done, and so avoid the risk of describing and naming the same material twice over. But the Kew Steudel has only hitherto been posted up by the aid of funds privately supplied on intermittent occasions, and is not absolutely complete.

Mr. Darwin having had occasion to appreciate the usefulness of such a work in the botanical investigations which have of late years engaged his attention, has determined to supply the funds for preparing a new edition of Steudel's "Nomenclator," brought up to date. The work, which it is estimated will extend over about six years, will be carried on at Kew, and will be based on the limitations of genera laid down in Bentham and Hooker's "Genera Plantarum," to which it will in fact form a kind of complement. The editorial work has been entrusted to Mr. Daydon Jackson, Secretary of the Linnean Society. Mr. Darwin's munificent aid does not extend beyond supplying the means for preparing the work. The form and manner of publication will be reserved for consideration on its completion.

The Royal Gardens, Kew, have been very fortunate in from time to time receiving sympathetic aid from the outside world on behalf of the various branches of scientific work carried on in connection with them. The gifts of Mr. Bentham's library and herbarium, of the Jodrell Laboratory, of the North Gallery, and now of the means of preparing a new Steudel, are conspicuous examples.

FIRE RISKS OF ELECTRIC LIGHTING

IN an article published originally in the United States, and reprinted in our contemporary, the *Chemical News*, Prof. Henry Morton has called attention to the risks to which property is exposed from the increasing employment of powerful currents of electricity for electric lighting. The caution and the remedies suggested are assuredly timely when preparations are being made on so many hands for a vast extension of electric lighting. No fewer than five times did fire break out in the late Paris Exhibition, and in each of these cases the cause was the same, namely, defective insulation of the conducting wires. Prof. Morton divides the dangers into two kinds—those arising from the conductors, and those arising from the lamps. When naked wires are used as conductors, and when both are, as is sometimes the case, merely nailed or stapled to wall or floor side by side, there is a great chance that some stray scrap of wire, a falling nail or pin, may short-circuit the line and become red-hot in an instant. Loose wires are again a source of danger, as they may be momentarily short-circuited, and arcs set up of a dangerous nature at the point of contact. These remarks are specially cogent in such cases as those where many arc lights are being worked on a single circuit, and where there is of necessity a very high electromotive force employed. On such circuits, moreover, should some of the arcs go out, there is a risk of the others becoming excessive in power, risking the metalwork of the lamps, and thereby endangering a conflagration. Moreover, the lamps themselves are not free from danger, if so constructed that fragments of red-hot carbon can fall from them, as was the case not many months ago with one of the Siemens' lamps in the reading-room of the British Museum.

As a remedy to diminish such risks, Prof. Morton makes the following recommendations, every one of which we can heartily indorse. Firstly, that both the conductors—the outgoing main and the return wire as well—should be completely insulated; and that the machines and fixtures of the lamps should also be insulated, so far as regards all ground connections. Secondly, that the outgoing and return wires, instead of being laid side by side, should be separated as widely as possible. And he also recommends that, in the case of arc lamps in series, there should be automatic adjustments, to short-circuit a part of the current in case the arc in the lamp becomes too powerful, and to diminish the electromotive force of the generators in proportion to the actual resistances in circuit. Even on those systems of electric lighting which apply the principle of incandescence, where the electromotive forces employed are, as a rule, smaller than with arc lighting, there is need of caution. And one cannot too highly admire the ingenious device with which Mr. Edison has met most of the possible obtions beforehand, by interposing automatic "cut-off" joints of lead wire at every branch of the ramified circuit of his system of supply; the thickness of the wire being adjusted according to the circumstances of each case. It would be well for Fire Insurance Companies to lose no time in laying down a code of reasonable conditions to be complied with in case of buildings lit by electric lights. Without such precautionary conditions electric lighting is at least as unsafe as lighting by gas, and that is saying a good deal. But where proper precautions are taken, we think it should be a far safer mode of lighting; and should be recognised as such by the imposition of a lower insurance premium than is fixed in the case of lighting by gas.

THE MARKINGS ON JUPITER

DURING the present winter months Jupiter will doubtless attract a large amount of attention from the possessors of telescopes. Displaying a large and varied extent of detail clearly indicating that atmospheric phenomena of stupendous character are in progress on his surface, this planet at once claims notice on account of the ease with which his chief features may be discerned, and their singular anomalies of motion and appearance made manifest.

The large red spot situated immediately south of the great southern belt, and lying parallel with it, continues to present a well-defined boundary, indeed we must attribute to this remarkable formation a good deal of the interest which has been accorded to this planet since the first apparition of the spot in the summer of 1878.

It has now been visible for a period exceeding three years, and its conspicuous and decided aspect as it nightly crosses the central meridian of Jupiter, sufficiently predicates that its existence is likely to be prolonged a considerable time yet. The spot is elliptical in form with tapering ends; it occupies about fifty-five minutes in its entire transit over the centre of the illuminated disc. No distinct alteration in its appearance has been recorded during the last two years. Minor changes have probably occurred, though too minute to be appreciable, for when we consider the perpetual state of commotion under which the other markings exist, we cannot regard this particular object as absolutely free from similar influences, though they may have hitherto eluded detection. One of the most recent measures of the spot give it a length of 29,000 miles, and a breadth of 8,300, so that the length is to the breadth as 7 to 2.

The telescopic history of this planet contains many instances of fairly persistent spots having been observed and utilised as a ready means of determining the period of the planet's rotation. But the records of former years can furnish no parallel to the extent and accuracy of the modern observations. The old observers were in a measure isolated, and their work often lacked corroboration. Circumstances are now changed entirely. Observers have become far more numerous, astronomical appliances have been greatly improved, and the science has become more popular with increased facilities, so that where one powerful telescope was found half a century ago, there are at least ten at the present day. The result is that all attractive phenomena, such as planetary markings, are eagerly watched and recorded, so that interesting comparisons and confirmations, impossible in former times, are often the natural outcome. In regard to the large spot on Jupiter it is certain that no previous observations can vie with it either in completeness or precision, and it must obviously supply the data for determining the rotation period of Jupiter with a degree of reliance beyond all parallel.

Proper motion in the spot itself originates a slight diffi-

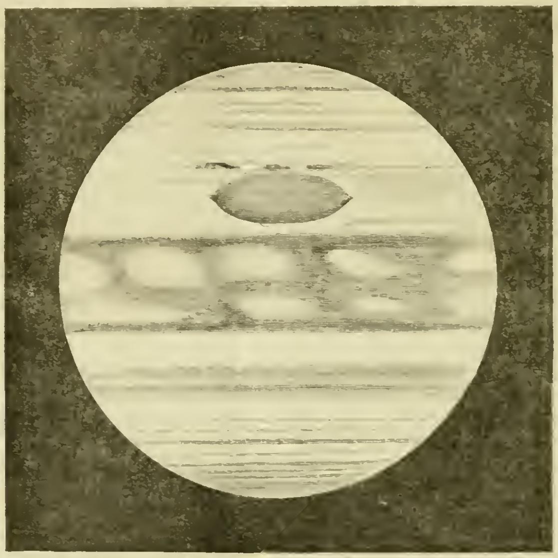

FIG. 1.—The great red spot in Transit, December 7, 1881, 1 h. 40m. There was a large white patch near the equator under the following side of the red spot. Immediately south of the red spot is a narrow belt with light and dark ovals upon it.

culty in adopting a period to satisfy the observations, and there is no doubt that similar independent movements in the objects observed were the cause of the differences in the periods assigned by various former authorities for the rotation which has varied from 9h. 49m. to 9h. 56m., and in truth it is doubtful whether we shall ever obtain the means of deriving the value with conclusive satisfaction. We can of course compute with nicety the periods of individual markings, but different ones have different periods. It is doubtful whether we can select the markings which are representative of the real period, for the spots are evidently influenced by a series of atmospheric currents which displace their relative positions on the disc in a very short interval of time. In the case of the great red spot, it has been surmised from its permanence and regularity of apparition that it very nearly represents the true rotating period of the planet's sphere, and it is gratifying to note that this element has been determined by several observers with excellent corroboration as follows:—

	h. m. s.	
Prof. G. W. Hough	9 55 35·2,	Sept. 79 to Jan. 27, 1881
A. Marth	9 55 34·47,	1878–81
J. F. J. Schmidt ...	9 55 34·42,	1879–80
H. Pratt...	9 55 33·91,	1879, July to December

These values are all within one second of the mean =9h. 55m. 34·5s. Several observers have remarked that the motion of the spot has slackened somewhat since 1879.

Turning now to the equatorial region of Jupiter, we shall find here not only a large extent of detail, but marked evidences of great and rapid changes. Immediately north and south of the equator there is a very well-defined dark belt, and between these are a series of

curious irregular shadings interspersed with brilliant white spots and light patches, which seem to be influenced by some abnormal phenomena. Watched from night to night, and their relative positions carefully determined, they are seen to vary considerably, and to travel much swifter than the red spot. The bright spots, which generally lie very slightly south of the equator and on the north border of the great south belt, are influenced by a rapid proper motion on the surface of the planet. In a single rotation of Jupiter they are displaced relatively to the red spot, to the extent of $3\frac{1}{4}°$, their period being $5\frac{1}{2}$ minutes less. In 1880 these white and generally oval spots were observed with a good deal of attention, and in a few marked cases the times of rotation were derived as follows:—

	h.	m.	s.
J. F. J. Schmidt	9	50	0
A. Marth	9	50	6·6
Prof. G. W. Hough	9	50	0·56
,, ,, ...	9	50	9·8
W. F. Denning	9	50	5

One bright spot in particular arrested attention as the most conspicuous of its class, and this object continues visible at the present time. Its independent motion enables it to make a complete circuit of Jupiter, relatively to the red spot, in $44\frac{1}{2}$ days. One of the most interesting points of observation is to note the changes in the relative positions of the spots on successive nights, and to watch the bright equatorial markings as they overtake and pass the red spot. In four days the white spots traverse an equivalent extent of longitude to that covered by the red spot, so that during this interval they travel from the *f.* end to the *p.* end of the latter object. The independent motion of the equatorial markings is the same in direction as that of the satellites and of the planet on its axis, namely, from west to east.

In the southern hemisphere of Jupiter there are several narrow dusky bands outlying the red spot, and a few dusky streaks or short belts of distinct form are manifest. In the north hemisphere there is a conspicuous double belt in about lat. 25°; the south side of this belt was

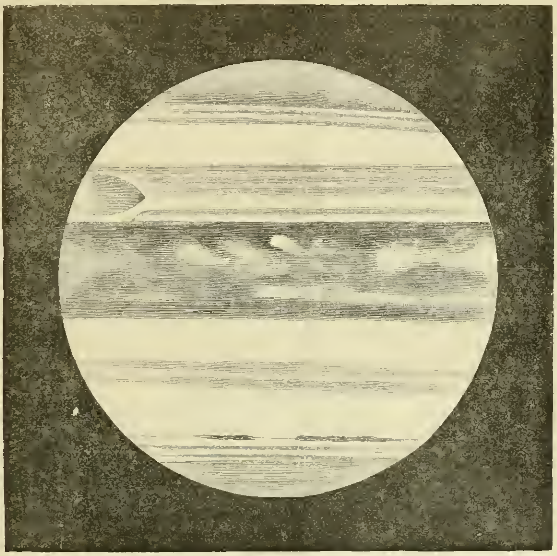

FIG. 2.—The bright spot in transit, December 18, 1881, 6h 12m. The following side of the red spot is seen on the western limb. To the east of the light spot, and in nearly the same latitude, is a dark mass emerging from the great southern belt.

formed by the outbreak and subsequent rapid development and dispersion of a series of dark spots during the months of October, November, and December, 1880. At first appearing as well-defined and almost as plain as the shadows of satellites in transit, they increased in numbers, or became greatly extended longitudinally, but gradually lost their decided character until they were eventually dispersed around the planet, and formed a dusky girdle considerably north of the equator. In fact the formation of a new belt on Jupiter had been going on under the eyes of observers.

As to the bright equatorial spot, it came to conjunction with the red spot on November 10, 1881, and the same objects were noted in conjunction on November 19, 1880, at 9h. 23m.. when crossing the central meridian of Jupiter. In the meantime the behaviour of the two objects has been very remarkable, for the red spot during the interval of 356 days has performed 861 rotations, while the light spot has completed 869, and has in fact travelled round the sphere of Jupiter eight times relatively to the position of the red spot! The two objects were again observed in the same longitude on December 24, 1881, at 9h. 43., having completed 967 and 976 rotations respectively. The next two conjunctions will occur on February 6, 1882, and March 23, 1882, after which they will not be well seen until the ensuing summer, when Jupiter again becomes visible in the morning sky, and the two spots, should they continue to be presented on the disc of the planet, will occupy nearly the same longitude on August 3, September 17, October 31, and December 14, 1882.

The diameter of the white spot is very variable, sometimes it is fully 2″, which corresponds to more than 4600 miles, but it is occasionally much contracted by encroachments

of the dark masses on the great northern belt. The spot is also liable to become very faint. I have carefully noted these variations, and though the observations are not sufficiently full to determine the period, if any, they show that the spot becomes faint almost to invisibility at intervals of about 56 days, and that increased brightness of the spot is accompanied with accelerated motion. I believe this particular object is a permanent feature on the planet, and that it lies far below the level of the dusky belts. Mr. Marth has determined from a discussion of the observations of 1880 and 1881 (to November) that the mean motion of the spot has been uniform, and this is important as a proof of its stability. My own numerous observations have led me to conclude that:—

1. It is self-luminous and light-emitting.

2. That it is a part of, or projection from, the actual surface of the planet.

3. That therefore it indicates the real rotation period of Jupiter, which is 9h. 50m. 6·6s. (= daily rate 878°·48), as deduced by Mr. Marth. The motion of the red spot shows a decided slackening, so that we cannot accept it as a reliable and invariable indication of the motion of the Jovian sphere with which probably it has no material connection.

These conclusions are supported by the fact that we cannot admit the idea of an object as permanent and conspicuous as the white spot, rushing on in advance of the already swift axial movement of the planet (as computed from the positions of the red spot) whereas we can more readily understand that atmospheric objects, such as the belts and red spot (which are forms of identical phenomena), would show a tendency to lag behind the rapid motion of the sphere. We must allow that there will be a failure of objects on the extreme outer envelopes of Jupiter, to keep pace with the tremendous velocity of objects on his real surface. The dusky belts, the red spot, and similar markings, are probably openings in the Jovian atmosphere, and the slackening motion of these objects is simply the indication that they are becoming more shallow than formerly, whence we may infer that the motion will continue to decrease until they are finally dissipated.

A comparison of my recent observations with those made by Gledhill and Welb in the years 1869-72, show that many of the features which they described and delineated (in the *Astronomical Register* and *Popular Science Review*) are still visible or have reappeared after an interval of obscuration. The great red spot may be the same object as Gledhill's ellipse of 1869-71. In many of the details visible then and now there is a remarkable similarity both in aspect and position, and the observers of Jupiter should further carefully investigate the physical appearance of the planet with a view to obtain more distinct evidence on the question of periodic variations. In this connection I may quote a remark by the late Mr. Lassell (*Monthly Notices*, vol. xxxiv. p. 310), where, in referring to round light spots he saw on Jupiter in March, 1850, and March, 1874, he says: "I believe the appearance of these spots is very rare, as I have not seen them for many years, and the general similarity of the aspect of the planet now [1874] and then [1850] suggests the idea that the various phases return in cycles, which I think more probable than that absolute secular changes occur in the heavenly bodies within the limit of time of any human records." W. F. DENNING

LITTLE ELECTROMOTORS

THE probability that within a few months almost every large town and city will be supplied with electricity on a large scale for the purpose of lighting, has brought into prominence the question of utilising the same supply for the purpose of producing power on a small scale for sundry domestic purposes. There are a number of objects for which machinery is employed, though on so small a scale that it would not be worth while to set up a steam-engine or gas-engine to drive it, to say nothing of the inconvenience of a steam- or gas-engine in a private house. To drive a sewing-machine, for example, or to work a light turning-lathe, requires a comparatively small power, and usually only for a limited time. It is natural then to think that when the power of electricity is available in the wires which supply electric light, such a power, especially as it is so simply and readily controlled, might be economically employed for such purposes.

But to drive machinery by electric currents necessitates the employment of the appropriate electric engine or "electromotor," which, as its name implies, is an engine which, by the expenditure of electrical energy, does mechanical work. Such engines have been known since 1831, when Prof. Henry first constructed a rotating engine driven by electromagnets. Ritchie, in 1833, independently constructed an electromagnetic apparatus for producing continuous rotation. Fig. 1, which we borrow from Prof. S. Thompson's "Lessons in Electricity and Magnetism," shows a modification of Ritchie's electromotor frequently found in collections of electrical apparatus. It consists simply of an electromagnet, C D, poised upon a

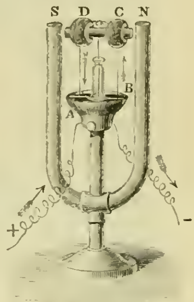

FIG. 1.

pivot between the poles, N S, of a steel horseshoe magnet, and fitted with an arrangement of mercury cups, A B, as a commutator, by means of which the current arriving through the wires is so directed through the coil as to produce motions, in one sense, only round the axis. The pole C of the electromagent is attracted round toward S until, just as it nears S the wire beneath C passes from one mercury-cup to the other, so reversing the current and causing C to be repelled from S and attracted to N.

To speak of the further developments of these machines in the hands of Jacobi, Sturgeon, Froment, and others, would be to traverse ground too wide for the scope of an article like this. Paccinotti's discovery of the ring-armature, which in 1869 he applied to the construction of an electromagnetic motor which was also capable of being used as a generator of currents, dropped strangely out of sight. And the subsequent discovery of M. Gramme that his generator would work as a motor was only the beginning of a new epoch in the history of electromotors. We know that all the magneto-electric and dynamo-electric machines used to generate continuous currents of electricity, whether of Gramme, Siemens, Brush, or Edison are *reversible*. If we drive them by mechanical power they yield electric currents, and if on the other hand we supply them with currents of electricity, they can run backwards and do work for us. Sawing and ploughing are now done every day by this means. We have Siemens' electric railway and tramway, and many other useful applications of the same principle, of which

one of the newest and most interesting is Dr. Hopkinson's electric elevator or "lift."

But to come back to the application of power on the very small scale adapted for domestic purposes; several *small* motors exist, each of which can do excellent work. The earliest of these small modern motors is that of M. Marcel Deprez, invented about three years ago, and which consists (see Fig. 2) of a single Siemens armature, A B, of the old well-known type, placed longitudinally between the poles of a horse-shoe, or rather a U-

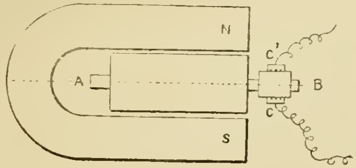

FIG. 2.

shaped steel magnet. The advantage of this arrangement is that the position of the armature utilises the whole field of force which lies between the limbs of the magnet. A large number of these little motors were set up by M. Marcel Deprez at different points of the galleries of the late Paris Exhibition in illustration of the possibility of distributing power from a central source. Two other forms of motor have more recently claimed attention. The first of these is the invention of M. Trouvé, and differs from that of M. Marcel Deprez in having an electromagnet instead of a permanent steel magnet to produce the field of magnetic force within which the armature is placed. The armature is also longitudinal and of the Siemens' type, with a slight modification, suggested by M. Trouvé, with the purpose of getting a more continuous action.

Fig. 3 shows how such a little motor may be attached

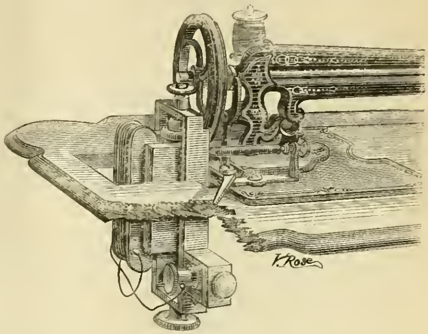

FIG. 3.

to a sewing machine. The axis of the armature is here vertical and carries a small disk or wheel of india-rubber which, when the motor is clamped in position, presses against the driving wheel of the sewing machine with a contact sufficient to enable it to drive the machine; a

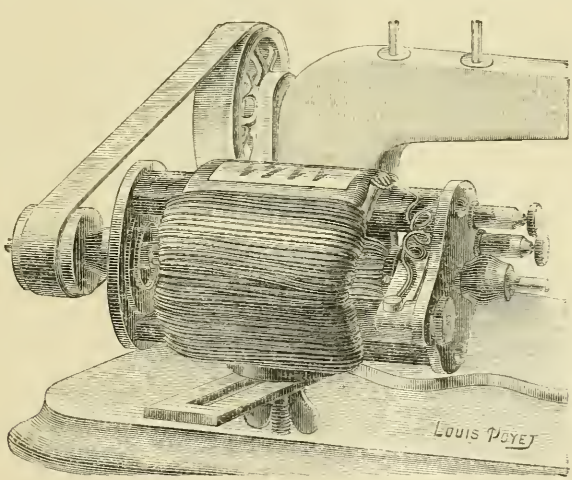

FIG. 4.

work which in spite of the small dimensions of the motor it accomplishes readily, on account of the high speed with which it runs. No steam-engine so small could possibly do the work without great loss, since steam will not give up its heat at an indefinitely great rate. It is said that three of Faure's accumulators weighing 50 lbs. each may, when fully charged, drive a sewing machine by a Trouvé motor for a whole week, working five or six hours every day. Motors similar to this have been fixed by M. Trouvé in his little electric canoe, and are suggested by M. Tissandier for balloon steering.

The favourite motor, however, at the present time appears to be that of Griscom, an American electrician, whose English agent is Mr. Paterson of Little Britain, and which we depict in Fig. 4. This elegant little machine is only $4\frac{1}{2}$ inches long, and weighs a little over two pounds only. But it is remarkably powerful and steady in its action. It can, when fed with a current of

requisite strength, rotate at a speed of 500 revolutions a minute. and in that time will do from 22 to 29 foot pounds of work. The construction is extremely simple. There is a Siemens' armature on a horizontal axis, within, and entirely surrounded by, the fixed electromagnet which not only serves to produce a powerful magnetic field, but also acts as a rigid framework for the rotating parts, which is thus protected from injury. The contact of the wires of the circuit with the commutator is made by two springs with little metallic friction-rollers at the end. The ironwork is made of malleable cast-iron, and so combines the advantage of high magnetic power and of cheap production. Mr. Griscom, the inventor, styles his little machine the double-induction motor on account of the reaction between the currents in the armature and those which supply the outer field-magnets. The inventor originally intended his motor to be used with a 6-cell bichromate battery, and he claims that one single charge of acid liquid will last long enough to enable a sewing-machine fixed to a motor to accomplish from 500 to 1000 yards of stitching. But there is no doubt that the motors work equally well with currents supplied from any other source in adequate strength. A gold medal was awarded at the late Paris Exhibition to Mr. Griscom for the excellence of his capital little machine.

It will be remarked that in each of the little modern motors described a simple Siemens' armature is employed in preference to one in the form of the Gramme ring or other complicated pattern. This is simply a consequence of the difficulty of constructing these more complex kinds of armature cheaply on a small scale. If they could be as cheaply constructed they would doubtless be preferable as having no dead points, and therefore not being liable to stick at starting, though this rarely happens with these little electric engines. It will also be noted that the last two forms are dynamo-electric instead of magneto-electric; that is to say their fixed magnets are electro-magnets of iron, not permanent magnets of steel. This is in order to gain space; for an electromagnet may be made far more powerful than a steel magnet of equal size, and therefore for an equal power the electromagnet will be of less bulk than the magnet of hard steel.

A CHAPTER IN THE HISTORY OF CONIFERÆ

THE PODOCARPEÆ

THE tribe is limited to three genera. Nothing is known as to the ancestry of two of these—*Microcachrys* and *Saxegothea*, represented now by a single species each; but the third, *Podocarpus*, comprises fifty-nine species according to Gordon.[1] The fruits are drupaceous or nut-like, and the seed generally possesses a hard shell and contains a dicotyledonous embryo. The leaves are either distichous, like the yew, or imbricated, and vary from very small to several inches in length; and although generally parallel-nerved, two species in the Kew Herbarium have distinctly dicotyledonous venation. Like the rest of the Coniferæ, some species form colossal trees, exceeding 200 feet in height. They are classified in the "Genera Plantarum" into four groups—*Nageia*, which contains the only Conifer indigenous to the East Indies; *Eupodocarpus*, comprising the vast majority of the species; *Stachycarpus*, and *Dacrycarpus*. The two latter sections are represented in the Eocene, and are at present limited to the Malay Archipelago, Australia, New Zealand, and South America. Notwithstanding their immense distribution and the evidence of vast antiquity which the genus presents, scarcely anything is known of their past history. In most cases the foliage when detached has little to distinguish it from better-known Coniferæ, and the fruits, in the fossil condition, seldom present anything by which their gymnospermous origin can be inferred. Except a doubtful and undescribed species from Aix-la-Chapelle, no podocarp is known of earlier age than Eocene, and they disappear from temperate Europe with the Oligocene. Like the Araucaria and other genera innumerable, they seem to oppose the theory that all plants have originated in northern regions, and passed south by way of existing continents; and unless it is supposed that their present distribution was accomplished prior to the Cretaceous, we are forced to admit, in order to explain their presence in Chili and other parts of South America, a land connection far to the south of that admitted by Wallace and those who share his opinions. No trace of podocarp has in fact been made known either from the Arctic or the American Cretaceous and Tertiary floras.

The fossil Podocarps that are known may be conveniently classified under two heads—those that have shed their leaves separately, and those that have shed them adhering to branchlets.

Of the former, various species have been described by Saporta, Heer, Unger, Ettingshausen, and others, ranging in time from the Suessonian to the lowest stage of the Aquitanian. They therefore form a group in Central Europe essentially characteristic of the Eocene, and are quite unknown in the Miocene, except in Italy. They occur at Aix, Lat. 43°, and extend up to about Lat. 48°, which represents their Eocene distribution as at present published. It may therefore emphasise the importance attaching to a proper examination of our British Eocene floras, when I state that they have now been found not only at Bournemouth, but in Antrim and in Mull, or as far north as about 56½°. The British species differs from all those previously figured, for it has a broadly sessile and articulated base, whilst the others are represented as tapering to a fine point. The leaves, though scarcely 2 mm. broad, sometimes reach 5 inches in length. Those from Mull, and, as far as can be seen, the half-leaf from Antrim, are specifically identical with the Bournemouth form, and this is the more remarkable since the latter is confined to the uppermost bed under the Coastguard Station, and has never been found in any of the other numerous beds from which I have so largely collected. Of the Continental species, the nearest to it are mostly from Aix, whose flora in several other respects presents the greatest affinities with ours. Besides the identity in appearance of some of the leaves with many existing Podocarps, as *P. andina*, the microscopic structure of the leaves and wood peculiar to them was recognised and explained by Unger. I have not seen any records of the fruits being found, and although some from Bournemouth might belong to the species, no essential character is preserved.

Of the Podocarps whose leaves are shed attached to branchlets, only the most insignificant traces have been hitherto known. I have now to add at least two species whose foliage, fruit, and flowers are preserved.

The first and most ancient is from Alum Bay, and has hitherto been supposed a Sequoia, a Taxus, a Cypress, &c., by distinguished Continental professors who have examined it. Possessing polymorphic foliage, it falls into the "Dacrycarpus" division of Hooker. By far the larger proportion of the foliage collected is distichous, being much smaller than that of the yew, with the bases of the leaves prolonged down and adhering to the stem, and with three out of the five rows, though still recognisable, reduced to small dimensions. This abortion of some of the leaves, in order to permit the remainder to expand into two lateral rows, is exceedingly characteristic of ancient Coniferæ, and still survives in Sequoia, being probably the precursor of the truly distichous arrangement seen in Taxus, Taxodium, Toveya, and other existing Conifers. The fruit is small, petiolated, and remarkable as occurring on the distichous branches. The fossils of Alum Bay were, unfortunately, collected principally for sale, and the unattractive imbricated branchlets and the insignificant-looking fruit were doubt-

[1] Sir Joseph Hooker believes they may eventually be reduced to less than orty, since several are very imperfectly known.

less passed over. The fruit I possess is attached to a branch, and was found during the last visit to Alum Bay on which I was able to collect any fossils, for within a few months of that time the leaf-bed disappeared with the recession of the cliff. It is the only Conifer known from Alum Bay, or even from the Lower Bagshot formation, and all others should be erased from the list.

The second species is from Bournemouth, and is known from even more ample material. The foliage is also dimorphic, the distichous type being however very subordinate and confined, as in *P. cupressina* and other living species, to short, simple branchlets. A complete seedling plant with its roots possesses an irregular distichous foliage something like that of the Alum Bay species, but becomes imbricated towards the root. The young plant seems to have retained this character for some time, as shown by several branchlets. It then appears to have assumed a semi-imbricated foliage, which is exceedingly graceful. The full-grown tree principally possessed imbricated foliage, and the position the distichous branchlets occupied can only be inferred from existing allies. The largest branch is about fifteen inches long, and is composed of about thirty branchlets; but this is surpassed in elegance by another seventeen inches long, whose stem is still imperfect. The simple branchlets are very slender, about six inches long, and were often shed singly, but both branches and branchlets, as I here term them, were, I think, articulated and shed naturally, and not broken off by wind. The fruit is a berry of about half an inch diameter, clustered in three, shortly stalked, and borne on an imbricated branch, and the male catkins are in pairs and terminal. The tree was probably of large growth, and pendulous. A third form, which I cannot assign with equal reason to any genus but Podocarpus, has larger foliage. Both of these types seem extinct, with their nearest allies in the Australian region and the Oriental Island region of Wallace.

In addition to these there are fruits from Sheppey which I believe to be podocarpous, one at least seeming identical with *P. elata* of Queensland. The whole of the forms will be published and fully illustrated by the Palæontographical Society in their usual exhaustive manner.

The study of the Tertiary Coniferæ, together with that of the ferns, has already led to some not unimportant rectifications. The Bovey Tracey beds have been exactly correlated with those of Bournemouth, and now the Mull, and I believe also the North of Ireland beds, can be clearly shown to be Eocene. I also hope in my next journey to Iceland to complete the correlation of the Tertiary beds there, and of Scotland and Ireland, with those of Greenland, which I cannot but regard, from whatever aspect they are viewed, as of considerably earlier age than Miocene.

J. STARKIE GARDNER

NOTES

WE are glad to see in the recently published number of the *Journal* of the Linnean Society Mr. Bentham's important paper on the *Gramineæ*, giving the critical results of his examination of the leading groups and genera of that important family. Having been read so recently as November 3, 1881, it has been printed and issued to the Fellows with commendable rapidity. We understand that our distinguished English botanist is, notwithstanding his recent severe domestic affliction and his advanced age, in excellent health, and that he is daily engaged in the Herbarium of the Royal Gardens, Kew, in the continued preparation of the *Genera Plantarum*—the monumental work on the genera of all known flowering plants, of which the first instalment was published in 1862. Sir Joseph Hooker and Mr. Bentham have been occupied with its elaboration for the last quarter of a century, and it will be with feelings of no small satisfaction that all students of systematic botany will learn that the printing of the third and concluding volume will shortly be commenced.

MESSRS. MACMILLAN AND CO. will shortly publish an account of the late Prof. James Clerk Maxwell, by Prof. Lewis Campbell, of St. Andrews, and Mr. William Garnett, late Fellow of St. John's College, Cambridge. We understand that Prof. Campbell was Maxwell's intimate associate in early life, and Mr. Garnett was associated with him as demonstrator at the Cavendish Laboratory from its opening in 1873 until Prof. Maxwell's death in 1879. The work will consist of (1) a biographical outline by Prof. Campbell, with selections from correspondence; (2) by Mr. Garnett, a popular account of Maxwell's chief contributions to science; and (3) a collection of his poems, a few of which are already known to the public, while the greater number of them will now be published for the first time. The book will be illustrated with one or more steel plates of portraits, and a series of outline sketches of early scenes, done by Prof. Maxwell's cousin, Mrs. Hugh Blackburn (J.B.), from drawings made by herself at the time; also with coloured and other diagrams explanatory of his scientific work, some of which are taken from original water-colour sketches of his own. Not to dwell here on Prof. Maxwell's eminence as a man of science—the originality and depth of his character, his religious earnestness, his amiability, and his quaint ironical humour, may be expected to render this presentation of him by intimate friends more than ordinarily attractive to many readers outside the scientific world. The whole will be comprised in an octavo volume of about 500 pages.

UNDER the direction of the Trustees of the Gilchrist Educational Trust a course of scientific lectures by Mr. Lant Carpenter has just been given in five Lancashire towns. The total audiences were from 3500 to 4000 per week, chiefly artizans, who maintained their interest to the very end—the same people coming night after night—and in some instances going to another town in the same week to hear the lecture over again. The lectures were well illustrated by experiments and by the photographic diagrams, &c., in the oxhydrogen lantern. The latest developments of science were treated of, including the storage of energy and the electrical transmission of power. At the close of the course, hearty votes of thanks (with requests for other courses) were passed to the Gilchrist trustees and to the lecturer.

THE staff of the Russian observing station on the Lena left St. Petersburg on December 27. MM. Yurgens and Eigner are intrusted with the astronomical, magnetical, and meteorological observations, and Dr. Bunge will make researches in zoology, botany, and geology. They expect to reach Irkutsk with their instruments, in two months, and to begin next spring their journey to Yakutsk, so as to be able to open the polar station at the mouth of the Lena, on August 1, 1882.

THE rate of the cricket's chirp varies with the temperature, becoming faster as the latter rises. Recently a writer in the *Salem Gazette* (Mass.) gave the following rule for estimating the temperature of the air by the number of chirps made by crickets per minute:—"Take seventy-two as the number of strokes per minute at 60° temperature, and for every four strokes more add 1°; for every four strokes less deduct the same." In a letter to the *Popular Science Monthly*, Margarette W. Brook gives an account of observations she made with a view to testing this rule, on twelve evenings, from September 30 to October 17. Her column of temperatures as computed by the rate of vibration shows a close agreement with that of temperatures recorded by the thermometer.

THE industrial manufacture of oxygen has engaged much thought, while the uses, on a large scale, of that agent have not been very exactly determined. At Passy there are now works

for producing the gas according to an improved method of MM. Brin frères, who attach the highest value to oxygen as an industrial agent, and indicate various applications of it. The process is the well-known one in which caustic baryta absorbs oxygen from the air, and gives it up under heat. By a special way of preparing the baryta, however (described in *Annales Industrielles*), they render it highly retentive of its absorbent power, obviating the necessity of frequent renewal. After 400 operations there was (on microscopical examination) no appreciable change. The baryta is placed, at Passy, in metallic retorts connected, in groups of fifteen, in two furnaces heated with gaseous fuel. A locomotive engine drives Root blowers, which force air into the retorts; after peroxidation the oxygen is liberated by heat, and pumped into the gasometer through an apparatus which removes traces of carbonic acid. As it is found that the peroxidation takes place better with moist than with dry air, the air is passed through a saturator on its way to the retorts. For production of 5000 cubic metres of oxygen a day in Paris, it is estimated (from the data at Passy) that the cost per cubic metre would be from 0·12 to 0·15 franc, according as coal or coke was used for fuel. The price of 100 kilogr. of baryta prepared by the new method is about 250 francs.

MILITARY surgeons are familiar with the remarkable attitude retained by soldiers who have died on the battle-field. Recent experiments by M. Brown-Séquard (*Comptes rendus*, December 26) throw some light on the phenomenon. It is proved (1) that a true muscular contraction may occur a certain time after as well as before death, and that this contraction may last long, and pass into the state of cadaveric rigidity, or disappear completely, so that one may then recognise the persistence of muscular irritability; (2) that of the different parts of the brain, the cerebellum has most power of producing contraction after death; (3) that the retention, by soldiers killed on the battle-field, of the attitude they had before death, depends not on a sudden occurrence of cadaveric rigidity, but on the production of a true contraction.

IN a paper lately read before the Royal Society of Tasmania, Sir J. H. Lefroy gives a new determination of the magnetic declination—8° 49'·3 E.—at Hobart for the year 1881, which he had made on the site of the old magnetical observatory of 1840-48. He notes the observation of Tasman in 1642, that "near the coast here" (Tasmania) "the needle points due north," and comparing this with the values obtained by some modern observers since 1840, he concludes that the declination which had been increasing up to the time of the magnetic survey made by Dr. Neumayer in 1863, is now decreasing. At Melbourne it has also been observed that the declination has been decreasing since 1865.

THE University of St. Petersburg has had added to it an astronomical observatory for the students. Until now the students who wished to learn practical astronomy have been reduced to make use of the very old observatory of the Academy of Sciences, with its old instruments and a complete want of any accommodation for study, or to find some friend among the officers of the Military General Staff Academy, who study at Pulkovo. Now St. Petersburg has a fine observatory, and will have an assistant-professor especially for this subject.

ST. PETERSBURG is to have its Electrical Exhibition, organised by the Technical Society. Several manufacturers of electrical apparatus and several Russian inventors have already promised their co-operation.

A VOLUME of considerable interest has recently been published by Friedenchsen and Co. of Hamburg—"Dr. Ludwig Leichhardt's Briefe an seine Angehörigen," edited by Dr. G. Neumayer and Otto Leichhardt, a nephew of the unfortunate Australian explorer. These letters are of special interest at present, when rumours come from Australia that the journals and other traces of Leichhardt have at last been found. The letters extend from 1834 (Göttingen) to April 3, 1848 (Macpherson's Station, Fitzroy Downs). These letters give one a high opinion of Leichhardt's qualifications for the work of exploration. He had an excellent education not only at home, but during lengthened residences in London and Paris. He had a strong love for natural science, was a shrewd and accurate observer, and a writer of considerable graphic power. His account of life in London and Paris is decidedly interesting, and his letters from Australia during his exploring work lead one to feel that the death of the writer was a real loss to science. These letters were quite worth publishing. Appended is a long paper by Dr. Neumayer on Leichhardt as a naturalist and explorer, in which the writer justly gives a high estimation of his qualifications and character.

THE Association for the Improvement of Geometrical Teaching will hold its annual meeting at University College, Gower Street, W.C., on Wednesday, January 11, at 11 a.m., when amongst other business the Code of Rules drawn up last April will be submitted for confirmation. The following resolutions will be proposed: That the proofs of the propositions contained in Book I. of the Syllabus will be received by the Association; and that the Committee for Elementary Plane Geometry be instructed to add a collection of exercises to the proofs of the propositions of the Syllabus. All persons interested in the objects of the Association are invited to attend.

THE number of visitors to the Royal Gardens, Kew, during the year 1881 was 836,676, the largest hitherto recorded.

AMONG the special articles in the *Annuaire* of the Brussels Observatory for 1882 are the following:—A list of 2000 communes in Belgium with their altitude according to the official survey; a paper on the conformation of the terrestrial globe; a series of studies of sun-spots in their various relations, by M. R. Tamene; tides on the coast of Belgium, by F. Van Rysselberghe; asteroids and comets discovered in 1881, by M. L. Niesten.

MR. E. C. OZANNE, of the Indian Civil Service, at present a student at the Royal Agricultural College, Cirencester, has been appointed Director of Agriculture in the Presidency of Bombay.

A SCHEME is on foot, having been approved by the Municipal Council of Paris, for extensively lighting with electricity the quarters of the Prefecture of the Seine, in the Tuileries. It is the work of M. Cernesson, and comprises lighting the Salle des Séances with eighty Swan lamps (in place of eighty Carcel lamps), and six Siemens' arc-lamps; lighting the library with forty-eight Maxim incandescent lamps (on the present lustres); another room with twenty-four Lane-Fox incandescent lamps; another with twenty Swan lamps; the Salle des Pas Perdus with two Werdermann lamps; a lobby with two Siemens' lamps, and a staircase with four Brush lamps. The whole will require an outlay of 75,000 francs. The horse-power necessary is 44, and while the idea of obtaining this from the Seine has been considered, it has been decided to set up a gas-engine in the court of the Tuileries. A portion of the motor force is to be employed for electric hoists, for driving ventilators, and other uses.

FROM the Annual Report of the Government Botanical Gardens at Saharunpur and Mussooree for the year ending March last, we gather the following facts:—On the collection and preparation of drugs, which seems to be an important item in the work of the establishment, it is stated that an indent for 200 lb.

of Taraxacum extract from the root of the Dandelion (*Taraxacum officinale*) was received from Calcutta. To supply this demand, which was the first occasion on which Taraxacum extract was supplied from the Saharunpur Garden, the seeds were sown over about half an acre of land in August, and the roots were dug up during the month of March and thoroughly dried in the sun, after which they were reduced to fine powder, this powder was then put into water and allowed to stand one night. The mixture was strained through fine cloth, and the clear liquid was then heated in a water bath until it had acquired the proper consistency. During the heating process a certain quantity of rectified spirits of wine was added to the extract. The heating process being finished, the extract on becoming cool was put into suitable jars and despatched. Of the Chuffa or Earth Almond, the tubers of *Cyperus esculenta*, a native of South Europe and North Africa, Mr. Duthie reports that about two dozen tubers have been received from Dr. Schomburgk, of Adelaide, and of this number about one-half had started into growth and were thriving luxuriantly. The tubers of this plant are used as an article of food in Egypt and in some parts of Europe, and they are now recommended for feeding sheep, hogs, poultry, &c., for which purpose they are largely used in the Southern States of America. Of Lucerne (*Medicago sativa*) it is stated that the demand for seed is every year increasing. "In addition to its good qualities as a fodder plant for horses and oxen it has the further advantage of being a perennial, which is very little affected by the extremes of heat and moisture it has to endure in North India. The Argan (*Argania sideroxylon*), a valuable oil-producing tree of Morocco, has been received at Saharunpur, and every care will be taken with the plants should the seeds germinate. Mr. Duthie says, "I find from a list published in 1854 by the late superintendent, that the tree then existed in the Saharunpur Garden. As none of the original trees are now to be found it would appear that the climate of this part of India is not altogether suitable."

UNDER the title of a "Catalogue of the Phænogamous and Vascular Cryptogamous Plants of Indiana" we have received a small octavo pamphlet, giving as we believe the first complete catalogue of the flowering plants and ferns of the well-known State of Indiana. The flora numbers 1432 species referred to 577 genera, and no doubt further additions will from time to time be made. The authors of the useful flora are the editors of the *Botanical Gazette* of Crawfordsville (J. M. and M. S. Coulter) and Prof. C. Barnes.

THE last number of the *Zapiska* (Memoirs) of the Caucasian branch of the Russian Geographical Society contains a valuable paper by the late P. K. Ushar, on the "Oldest Traditions on Caucasus."

WE have just received the first part of a second series of Dr. C. Fr. W. Krukenberg's "Vergleichend-physiologische Studien," Heidelberg, 1882. This part, of over 180 pages, is taken up with a number of very important and interesting memoirs, on such subjects as "On the Temperature at which the Lymph of Invertebrates Coagulates," "On the Colour Substance of Feathers," "On the Protective Coverings of the Echinoderms," &c.

THE Polytechnic has at last been sold, and will finally close on January 21. Until then a varied programme will be presented daily, including new musical, optical, magical, and popular scientific entertainments, as well as a *réchauffé* of very many of those that have been characteristic of the place during the last twenty years.

A VERY favourable Report is to hand of the Sheffield Free Public Libraries and Museum. Many additions have been made to the latter, and the small observatory attached, and which is open to the public, was visited during the year by about 3000 people.

ON December 29, 1881, two strong shocks of earthquake were felt at Kiangari, in the province of Kastamoumi. The movement was from east to west. Considerable damage was done to the village, but no details have yet been received at Constantinople.

WE have received from the Society of Telegraph Engineers a list of the additions to their library during the past year; this library, we may remind our readers, is now open to the public.

THE Waterford Literary and Scientific Association have begun to publish their Proceedings. The part for 1880-81 contains abstracts of various lectures and papers, and the fifth Annual Report records the steady success of the Association.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. Wm. Trent; a Marsh Ichneumon (*Herpestes galeri*) from South Africa, presented by Mr. Ernest Wells; an Indranee Owl (*Syrnium indranee*) from Ceylon, presented by Commander Burkitt; a Short-toed Lark (*Calandrella brachydactyla*), British, presented by Mr. H. A. Macpherson; a Pike (*Esox lucius*), British fresh waters, presented by Mr. George Seaton; a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, a Kinkajou (*Cercoleptes caudivolvulus*) from Brazil, a Black-footed Penguin (*Spheniscus demersus*) from South Africa, deposited; a Kusimanse (*Crossarchus obscurus*) from South Africa, a White eared Conure (*Conurus leucotis*) from Brazil, a Blue crowned Parrot (*Tanygnathus luzonensis*) from the Philippines, purchased; a Molucca Deer (*Cervus moluccensis*), born in the Gardens.

PHYSICAL NOTES

THE vapour-tension of liquid mixtures has been lately investigated by Herr Konowalow (*Wied. Ann.*, No. 9) in the case of the first four members of the alcohol and the acid series, each mixed, in various proportions, with water. Curves were obtained by taking the percentages as abscissæ and the tensions as ordinates. The author finds that each mixture, to which a maximum or minimum of tension corresponds, has, at the temperature indicated, the same composition as its vapour. Thus liquid mixtures, with reference to distillation, are divisible into three groups—(*a*) Those whose curve of tension has neither a maximum nor a minimum; (*b*) Those whose curve has a maximum (*e.g.* propylic alcohol, butyric acid); (*c*) Those whose curve has a minimum (*e.g.* formic acid). Herr Konowalow shows, from a table of all the constant boiling mixtures known to him, that in all the boiling temperature of the mixture is either greater or less than those of both constituents, *i.e.* all the tension-curves have a maximum or a minimum. The existence of such a point seems, thus far, to be a necessary condition of the existence of a constant boiling mixture. These mixtures have not, apparently, a simple molecular constitution.

IN his study of sulphur Saint-Claire Deville obtained (from flowers of sulphur) a variety more stable than those known, and insoluble in sulphide of carbon; its form being that of a fine powder, each grain a hollow vesicle. He failed to find the specific gravity of this vesicular sulphur, and suggested to M. Spring, about a year ago, to subject the material to the powerful compressing apparatus used in his recent noteworthy experiments. This has been done (*Bull. Belg. Acad.* No. 8), with a pressure of 8000 atmospheres for a few seconds and temperature of 13°, producing hard pale yellow blocks. Treatment with sulphide of carbon showed that 4·21 per cent. was transformed into octahedral sulphur, so that the density of the vesicular variety is less than that of the other. M. Spring further directly determined the specific gravity of those blocks at different temperatures, measuring the expansion; and by calculation he reaches the result that vesicular sulphur has probably the same specific gravity as prismatic sulphur (1·960). It was also observed that vesicular sulphur dilates regularly under heat up to 43°, beyond which it contracts continuously, till at 80° it has the same specific

gravity as at zero. This contraction M. Spring thinks probably due to transformation of vesicular into octahedral sulphur

In another paper to the Belgian Academy (*Bull.* No. 8) M. Spring concludes that there is a relation between the dilatation and the atomic weight of simple substances; for certain of them, as sulphur, selenium, and tellurium, nickel and cobalt, iron and aluminium, the former is inversely proportional to the latter. Otherwise expressed, the dilatation per atom (in the groups specified) is constant. The possibility is thus suggested of determining the number of atoms contained in a molecule of a solid substance. M. Spring is investigating this.

Prof. W. Holtz, inventor of the well-known Holtz electrical machine, has recently studied the various possible ways of arranging the inductors and armatures of his machine. This research was undertaken with a view partly to investigate the action of the analogous machine of Töpler, in which the fixed plate is not pierced as in the Holtz machine, and partly to ascertain the reasons for the shifting brushes of light to be observed in the ordinary Holtz machine. The research, which is too lengthy to reproduce here, led to the conclusion that there is an advantage in the apertures of the fixed plate.

To charge the electrodes of a secondary battery to their maximum potential requires a quantity of electricity roughly proportional to their surface. But if the source from whence the charge is derived is of an electromotive force inferior to this maximum, then the polarisation-charge is limited, not by the surface of the electrodes merely, but by the fact that the opposing polarisation completely stops the current. M. Blondlot has lately determined the quantities of charge required to polarise to such a limit a voltameter of given electrodes, when the electromotive forces are also of given magnitude. This was done by using a voltameter with very small electrodes, and including in the circuit with it a battery, a ballistic galvanometer, and an apparatus for closing circuit during a determinate fraction of a second. By the device of increasing the area of one or other of the electrodes, M. Blondlot was able to study independently the two cases of polarisation by oxygen and of polarisation by hydrogen. The author further shows (*Journal de Physique*) that the elementary capacity of an electrode for a given electromotive force does not depend on the nature of the electrode. The latter is also proved by a single qualitative experiment. It follows that to charge, by an instantaneous polarisation, the electromotive force between an electrode and electrolyte of value e_1 to a value e_2, the same quantity of electricity is always required, whatever the chemical nature of the electrolyte. Further, the charge of the double electric layer at the surface of contact of an electrode and electrolyte does not depend on the nature of the electrolyte if the electric difference remains the same. M. Blondlot has also given an absolute measure of the initial capacity of platinum in water acidulated by sulphuric acid, and shows that this capacity may vary under different influences.

GEOGRAPHICAL NOTES

The *Journal* of the Geographical Society of Tokio for the year 1881 has just been published. It is printed wholly in the Japanese character, and its contents are therefore inaccessible to all but a very few European readers. Besides reports of the meetings, and some other official information, it contains a paper on Saghalin and the Kurile Islands, and one on the historical geography of Japan. Some Japanese who have travelled in China have formed themselves into a society for publishing a topographical description of that country. This will contain little that will be new to English readers, as no Japanese has, we believe, penetrated into Central Asia from the side of China. The Japanese have given us much new information respecting Corea, but they have as yet added little else to our geographical knowledge.

Mr. E. C. Hore's paper on Lake Tanganyika forms the staple of the January issue of the Geographical Society's *Proceedings*. The two maps which Mr. Hore furnishes are a valuable addition to the cartography of the lake, which is now for the first time delineated with any pretence to accuracy as a whole. The map of the southern part of the lake, Livingstone's Lake Liemba, is on the scale of five geographical miles to the inch. Mr. Markham's paper on the *Jeannette* expedition and Commodore Jansen's notes on recent Dutch Arctic voyages, and Mr. Leigh Smith's probable position we have already referred to at some length, and in connection therewith need only add that a map is now given of Wrangel Island from Lieut. Berry's survey. The geographical notes bring us some interesting news of African exploration, chiefly on the east side of the continent, and hold out the hope of a future paper on the little-known interior of Mozambique by a new traveller.

The first seven sheets of the large map of Eastern Equatorial Africa, with the preparation of which Mr. Ravenstein was entrusted in 1878 by the Council of the Geographical Society, are at last ready for issue by Mr. Stanford.

Dr. Harmand, who has for some time been an assistant secretary of the French Geographical Society, and has lately been appointed Consul for France at Bangkok, is shortly to avail himself of the opportunity thus offered for making natural history and ethnographical collections in the Indo-Chinese peninsula.

We have received parts 27–29 of the new edition of Stieler's Hand Atlas, containing the following maps:—A railway and steamer map of Germany and neighbouring countries; Austria-Hungary; India and Inner Asia, northern sheet; a meteorological chart of the world; Iran and Turan; general map of South America; sheet 4 of the six-sheet map of South America; North-East Africa and America; South Africa and Madagascar. Other three parts, containing eight maps, will conclude the new issue of this Standard Atlas, which will have ninety-five maps in all.

The *Deutsche Geographische Blätter* (Heft 4 Band 10) of the Bremen Society contains the narrative of the brothers Krause, sent by the Society to explore the Behring Straits region, mainly for commercial purposes. Capt. Koldeway contributes a paper on the position of the Arctic ice during the past summer, which was peculiar in some respects; Capt. Koldeway shows that it was dependent on meteorological conditions with which we are imperfectly acquainted, but for a knowledge of which the Arctic observing stations ought to do much. There is also a useful summary of the Arctic work of the year, in which it is claimed for Capt. Dallmann that he was the first to land on Wrangel Land in 1866. In a note on p. 448 of the "Voyage of the *Vega*," vol. i., Baron Nordenskjöld, however, thinks it strange that Dallmann should only now have mentioned this voyage.

Since 1873, Herr Dietrich Reimer of Berlin has published at intervals important contributions to the literature of African exploration, under the title of "Beiträge zur Entdeckungsgeschichte Afrika's." The first issue was a series of small maps showing the progress of a general knowledge of Africa from antiquity down to the nineteenth century. The second contains a paper on the part taken by Germany in African exploration, and a map, with text, showing what the various nationalities have done for African exploration during the nineteenth century. The third issue is a volume containing the journal of Dr. Paul Pogge during his exploration of the Lunda States, in the southern basin of the Congo in 1875-6. The fourth volume gives a narrative of Herr Otto H. Schütt's exploration on the Lower Quanza in 1877-9. These are all of considerable value, especially the two last issues, which contain the results of much detailed work by competent scientific observers. We trust Herr Reimer will be encouraged to continue his enterprise.

The Vienna Geographical Society celebrated the twenty-fifth anniversary of its foundation on December 22 last. The Society numbers 74 honorary and 644 ordinary Members; its library consists of nearly 11,000 works.

The geographical weekly *Das Ausland* has changed hands. Up to December 31 last its editor was the well-known geographer, Fr. von Hellwald; his place is now taken by Prof. Friedr. Ratzel of Munich. The paper will in future confine its contents solely to geographical and ethnographical subjects.

ACTION OF FREE MOLECULES ON RADIANT HEAT, AND ITS CONVERSION THEREBY INTO SOUND[1]

The lecture opens with a brief reference to the researches of Leslie, Rumford, and Melloni. The labours of Tyndall and Magnus, as far as they bear upon the present subject, are then succinctly sketched, their points of difference being

[1] Abstract of the Bakerian Lecture, by J. Tyndall, F.R.S., given at the Royal Society, November 24, 1881.

signalised and briefly discussed. This preliminary sketch is wound up by a reference to a recently published paper by Lecher and Pernter, who, while supporting the lecturer in the matter of gases, dissent from him in the matter of vapours. These investigators are especially emphatic in affirming the neutrality of aqueous vapour to radiant heat. Following Magnus, they refer Tyndall's results to what Magnus calls "vapour-hesion," that is to say, to the condensation of the vapours on the surfaces of the plates of rock-salt used to close the experimental tube, and on the interior surface of the tube itself.

In November, 1880, the lecturer's investigations in this field were resumed. Former experiments were repeated and verified with divers sources of heat, and with various experimental tubes—some polished within, and others coated inside with lampblack. The results obtained with the one class of tubes are substantially the same as those obtained with the other.

But even a coating of lampblack may be supposed to reflect a certain amount of heat, hence the desirability of an arrangement whereby internal reflection should be entirely abolished. This was accomplished in the following manner:—A spiral of platinum wire, rendered incandescent by a voltaic current of measured strength, was chosen as source of heat. An experimental tube 38 inches long and 6 inches in diameter had two circular apertures at its ends, closed by transparent plates of rock-salt, 3 inches in diameter. The tube was furnished with three cocks—one connected with a large Bianchi's air-pump; another with a purifying apparatus; while through the third vapours and gases could be admitted. Prior to entering the tube the calorific rays were sent through a very perfect rock-salt lens, by means of which an image of the spiral was formed on the most distant plate of rock-salt. To obtain the image with clearness, the spiral was first rendered highly luminous, and afterwards reduced, by the introduction of resistance, to the required temperature. In this way a calorific beam was sent along the axis of the experimental tube without at all impinging upon its interior surface. No reflection came into play; no absorption by hypothetical liquid films, coating the internal surface, could occur; and yet experiments made with this arrangement entirely confirmed the preceding ones, wherein by far the greater quantity of heat which reached the pile had undergone reflection.

When the source of heat was changed to a carefully-worked cylinder of lime, a portion of which was rendered incandescent by an ignited stream of coal-gas and oxygen, the results were confirmatory of those obtained with the spiral. The order of absorption in both cases was the same, the only difference being that the fractional part of the total radiation absorbed in the case of the lime-light was less than that absorbed in the case of the spiral.

To condense the radiation from the lime-light, concave mirrors were sometimes employed, and sometimes rock-salt lenses. The results in both cases were identical.

An experimental tube of the dimensions here given was employed by the lecturer to check his results more than ten years ago. Its interior surface was rough and tarnished, and when warmed dynamically by the entrance of a gas its power as a radiator enabled it to disturb, to some slight extent, the purity of the results. To obviate this, the experimental tube recently employed was provided with an internal silver surface, deposited electrolytically and highly polished. By this arrangement the radiation of the tube itself, as well as its absorption, was rendered quite insensible.

The rock-salt plates used to close the experimental tube, and on which liquid films are alleged to be deposited, remain to be examined. In this case also an *experimentum crucis* is possible. If the observed absorptions be due to such liquid films, then the separation of the salts more widely from each other, the space between them being copiously supplied with vapour, ought to produce no effect; but if the absorption, as alleged by the lecturer, be the act of the vapour molecules, then the deepening of the absorbing stratum ought to produce an augmented effect. For many gases and some vapours this problem was solved as far back as 1863. By means of an apparatus then described, polished plates of rock-salt could be brought into contact with each other, and then gradually separated, until the gaseous stratum between them was some inches in depth. With sulphuric ether vapour, the distance between the plates being one-twentieth of an inch, an absorption of 2 per cent. was observed. With a thinner stratum, or a weaker vapour, even this small absorption vanished, while in passing from one-twentieth of an inch to two inches the absorption rose from 2 per cent. to 35 per cent. of the total radiation. Such experiments, recently verified, entirely dispose of the hypothesis that liquid films were the cause of the observed absorption.

The "vapour-hesion hypothesis" involves the assumption that liquids exert on radiant heat an absorbent power which is denied to their vapours. It assumes, in other words, that the seat of absorption is the molecule considered as a whole, and not the constituent atoms of the molecule. For were the absorption intra-molecular, the passage from the liquid to the vaporous condition, which leaves the molecules intact, could not abolish the absorption. So far back as 1864 the lecturer had proved that when vapours, in quantities proportional to the densities of their liquids, were examined in the experimental tube, the order of their absorptions was precisely that of the liquids from which they were derived. This result has been recently tested and verified in the most ample manner by means of the apparatus in which internal reflection never comes into play. It furnishes, therefore, the strongest presumptive evidence that the seat of absorption in liquids and in vapours is the same.

As a problem of molecular physics it was, however, in the highest degree desirable to compare together *equal* quantities, instead of proportional quantities, of liquids and vapours. Highly volatile liquids alone lend themselves to this experiment, for only from such liquids can vapours be obtained sufficient, when caused to assume the liquid form, to produce layers of practicable thickness. Two cases, however, have been very fully worked out, the substances employed being the hydride of amyl and sulphuric ether. Careful and exact experiments, many times repeated, lead to the result that when the number of molecules traversed by the calorific rays in the vapour is the same as that traversed in the liquid, the absorptions are identical. In the silvered experimental tube, which, as stated, is 38 inches long, hydride of amyl vapour, at a mercury pressure of 6·6 inches, is equivalent to a liquid layer 1 millim. in thickness, while a vapour column of sulphuric ether, of the same length, and 7·2 inches pressure, would also produce a liquid layer 1 millim. thick. The experiment has been made with the utmost care, both with the lime-light and the incandescent platinum, with the result that it is impossible to say that there is any difference between the vapour absorption and the liquid absorption. In the face of such facts the "vapour-hesion" hypothesis, as an explanation of the results published by the lecturer, cannot be sustained.

On November 29, 1880, he had the pleasure of witnessing, in the laboratory of the Royal Institution, the experiments of Mr. Graham Bell, wherein a concentrated luminous beam, rendered intermittent by a rotating perforated disk, was caused to impinge upon various solid substances, and to produce musical sounds. Mr. Bell's previous experiments upon selenium naturally led him to conclude that the effect was produced by the luminous rays of the spectrum. The contemplation of these experiments produced in the lecturer the conviction that the results were due to the intermittent absorption of radiant heat. He was experimenting on vapours at this time. Substituting in idea gaseous for solid matter, he clearly pictured the sudden expansion of an absorbent gas or vapour at every stroke of the calorific beam, and its contraction when the beam was intercepted. Pulses far stronger than those obtainable from solid matter would probably be thus produced, which, when rapid enough, would generate musical sounds. The intensity of the sound would, of course, be determined by the absorptive power of the gas or vapour.

This idea was tested on the spot. Placing sulphuric ether in a test-tube, and connecting the tube with the ear, the intermittent beam was caused to fall upon the vapour above the liquid. A feeble musical sound was distinctly heard. Formic ether was tried in the same way, and with the same result. Bisulphide of carbon was then tried, but the vapour of this liquid proved incompetent to generate a musical sound. These results, which were in perfect accordance with those previously enunciated by the lecturer, were first made public during a discussion at the Society of Telegraph Engineers on December 8, 1880 (*Journal of Telegraph Engineers*, vol. ix. p. 382).

It was obvious, however, that the arrangement of Mr. Bell—a truly beautiful one—was not suited to bring out the maximum effect. He had employed a series of lenses to concentrate his beam, and these, however pure, would, in the case of transparent gases, absorb a large portion of the rays most influential in producing the sound. The lecturer, therefore, resorted to lenses of rock-salt and to concave mirrors silvered in front. He

employed various sources of heat, including that of the electric lamp. The lime-light he found very convenient. With the lime-light and concave mirror, sounds of surprising intensity were produced by all the highly absorbent gases and vapours. Among gases chloride of methyl was loudest. Conveyed directly to the ear by a tube of india-rubber, the sound of this gas seemed as loud as the peal of an organ. Abandoning the ear-tube, and choosing a suitable recipient for the gas, the sounds were heard at a distance of 20 feet from their origin. As regards intensity, the order of the sounds, in gases, corresponds exactly with the order of their absorptions of radiant heat.

Among vapours sulphuric ether stands highest, this result being in part due to the great volatility of the liquid. But the intensity of the sound is by no means wholly dependent on volatility. The specific action of the molecules on radiant heat is as clearly shown in these experiments as in those previously conducted with the experimental tube and thermopile. Upwards of eighty vapours have been tested in regard to their sound-producing power.

With regard to aqueous vapour, whose action upon radiant heat even the latest publications on this subject describe as *nil*, it was especially interesting to be able to question the vapour itself as to its absorbent power, and to receive from it an answer which did not admit of doubt. A number of bulbs about an inch in diameter were placed under the receiver of an air pump, with a vessel containing sulphuric acid beside them. When thoroughly dry they were exposed to an intermittent beam. The well-dried air within the bulbs proved silent, while the slightest admixture of humid air sufficed to endow it with sounding power. Placing a little water in a thin glass bulb, and heating it nearly to its boiling point, the sounds produced by the developed vapour are exceedingly loud. The bulbs employed in these experiments are usually about a cubic inch in volume. They may, however, be reduced to one-fiftieth or even one one-hundredth of a cubic inch. When a minute drop of water is vaporised within such little bulbs, on their exposure to the intermittent beam loud musical sounds are produced.

It is to be borne in mind that the heat employed in these experiments, coming as it did from a highly luminous source, was absorbed in a far smaller degree than would be the heat from bodies under the temperature of incandescence.

To render the correlation of sound-producing power and adiathermancy complete, all the gases and vapours which had been exposed to the intermittent beam were examined as to the augmentation of their elastic force through the absorption of radiant heat. A glass cylinder, 4 inches long and 3 inches in diameter, had its ends closed with transparent plates of rock-salt. Connected with this cylinder was a narrow U-tube, containing a coloured liquid which stood at the same level in the two arms of the U. The cylinder could be exhausted at pleasure or filled with a gas or vapour. When filled, the sudden removal of a double-silvered screen permitted the beam from the lime-light to pass through it, the augmentation of elastic force being immediately declared by the depression of the liquid in one of the arms of the U-tube and its elevation in the other. The difference of level in the two arms gave, in terms of water-pressure, a measure of the heat absorbed. With the stronger vapours it would be easy with this instrument to produce an augmentation of elastic force corresponding to a water-pressure of a thousand millimetres. As might be expected the intensity of the sounds corresponded with the energy of the absorption, varying from "exceedingly strong," "very strong," "strong," "moderate," "weak," to "inaudible." In this connection reference was made to the interesting experiments of Prof. Röntgen, an independent and successful worker in this field.

In conclusion, the lecture draws attention to the bearing of its results upon the phenomena of meteorology. The views of Magnus regarding the part played by mist or haze, are referred to and attention is directed to various observations by Wells which are in opposition to these views. The observations of Wilson, Six, Leslie, Denham, Hooker, Livingstone, Mitchell, Strachey, and others are referred to and connected with the action of aqueous vapour upon solar and terrestrial radiation. Many years ago the lecturer sought to imitate the action of aqueous vapour on the solar rays by sending a beam from the electric light through a layer of water, and afterwards examining its spectrum. The curve representing the distribution of heat resembled that obtained from the spectrum of the sun, the invisible calorific radiation being reduced by the water from nearly eight times to about twice the visible. Could we get above the screen of atmospheric vapour, a large amount of the ultra-red rays would assuredly be restored to the solar spectrum. This conclusion has been recently established on the grandest scale by Prof. Langley, who on September 10 wrote to the lecturer from an elevation of 12,000 feet on Mount Whitney, "where the air is perhaps drier than at any other equal altitude ever used for scientific investigation." An extract from Prof. Langley's letter will fitly close this summary :—"You may," he says, "be interested in knowing that the result indicates a great difference in the *distribution* of the solar energy here from that to which we are accustomed in regions of ordinary humidity, and that while the evidence of the effect of water-vapour on the more refrangible rays is feeble, there is, on the other hand, a systematic effect due to its absence, which shows, by contrast, its power on the red and ultra-red in a striking light. These experiments also indicate an enormous extension of the ultra-red rays beyond the point to which they have been followed below, and being made on a scale different from that of the laboratory—on one indeed as grand as nature can furnish—and by means wholly independent of those usually applied to the research, must, I think, when published, put an end to any doubt as to the accuracy of the statements so long since made by you, as to the absorbent power of water-vapour over the greater part of the spectrum, and as to its predominant importance in modifying to us the solar energy."

SOCIETIES AND ACADEMIES

London

Royal Society, December 8.—"On the Electrolytic Diffusion of Liquids," by G. Gore, LL.D., F.R.S. In this communication the author has described an apparatus, and an attempt made with it, to ascertain more definitely than he was able in a previous research (on "the Influence of Voltaic Currents on the Diffusion of Liquids," *Proc.* Roy. Soc., No. 213, 1881) whether, when an electric current is passed vertically through the boundary surface of mutual contact of two electrolytes lying upon each other in a narrow vertical glass tube, the mass of either of the liquids expands or moves as a whole in the line of the current, and also to obtain additional data to assist in explaining the phenomena observed in the previous research.

The results obtained with a solution of mercuric nitrate (sp. gr. 1·30) below, and a solution of cupric nitrate (sp. gr. 1·22) above, showed, first, and most conclusively, that the upper liquid diffused downwards continuously through the meniscus in the glass tube (the meniscus remaining motionless) during the passage of an upward electric current; and second, that either no manifest expansion occurred in the liquid next the cathode in the upper solution, and that equal volumes of liquid diffused in two opposite directions through the meniscus; or that any expansion of the upper liquid was compensated for by downward diffusion of an equal bulk of that liquid. Another possibility was that the united volumes of metallic-electro deposited copper, and of the acid element from which it had been separated by electrolysis, were greater than before such separation, and that this was exactly compensated by the volume of liquid diffused downwards through the meniscus.

Zoological Society, December 13.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. Sclater exhibited and made remarks on two skins of a Rail from Macquarie Island, south of New Zealand, which had been sent to him by Sir George Grey, K.C.B.—Mr. H. Seebohm exhibited and made remarks on specimens of the Rusty Grakle (*Scolecophagus ferrugineus*) and Pallas's Great Grey Shrike (*Lanius major*), which had been shot near Cardiff, and were new to the British avifauna.—A communication was read from Mr. Clements R. Markham, F.R.S., containing an account of his researches into the former whale-fishery of the Basque Provinces of Spain.—Messrs. J. J. Lister and J. J. Fletcher read a paper on the condition of the median portion of the vaginal apparatus in the Macropodidæ, in which they arrived at the following conclusions :—(1) In the Macropodidæ the median vaginal canal is closed in early life. (2) In the genera *Macropus*, *Halmaturus*, and *Petrogale* (and perhaps also *Dorcopsis* and *Dendrolagus*) an opening is formed, leading directly from the median vaginal canal into the urogenital sinus, which opening most probably gives passage to the young. This opening may be formed early in life, as is usual in the genus *Halmaturus*, or not till young are about to be

produced, as in *Macropus rufus*. (3) The evidence with regard to *Macropus major* is conflicting; in one case the median canal has been found open after parturition, and in two others closed. (4) In *Hypsiprymnus gaimardi* (and probably also *H. murinus*) the median canal remains closed, and the young passes down the lateral vaginal canals, which present a different structure from that found in the other examples of Macropodidæ.—A communication was read from the Rev. Canon Tristram, containing the description of a new Fruit-Pigeon of the genus *Carpophaga*, from the Louisiade Archipelago, which he proposed to name *Carpophaga salvadorii*.

Geological Society, December 7.—Mr. R. Etheridge, F.R.S., president, in the chair.—William Amherst Tyssen Amherst, M.P., Robert Edward Cresswell, W. R. Eaton Hodgkinson, Simon D. Macdonald, Rev. Edward Cook Pritchard, Rev. Alexander Simpson, B.Sc., Prof. William Waagen, Ph.D., Frederick John Webb, and Charles Henry Wilson, were elected Fellows of the Society.—Mr. W. Topley made a statement respecting the International Geological Congress at Bologna.—Prof. Judd, at the request of Prof. John Milne, of the Imperial Engineering College of Tokio, Japan, called the attention of the Members of the Society to the important work now being carried on by the Seismological Society of Japan. Geologists could become Members of the Seismological Society of Japan (which stands greatly in need of help) by an annual payment of 1*l.*, which will entitle them to receive the whole of the publications of the Society. Prof. Judd was prepared to receive the names of Members on behalf of Prof. Milne.—The following communications were read:—The zones of the Blackdown beds and their correlation with those at Haldon, with a list of the fossils, by the Rev. W. Downes, B.A., F.G.S.—On some new or little-known Jurassic Crinoids, by P. Herbert Carpenter, M.A. Communicated by Prof. P. Martin Duncan, M.B. Lond., F.R.S., F.G.S.—Notes on the Polyzoa of the Wenlock shales, Wenlock limestone and shales, over the Wenlock limestone. From material supplied by G. Maw, F.L.S., F.G.S. By G. R. Vine. Communicated by Dr. H. C. Sorby, F.R.S., V.P.G.S.

Anthropological Institute, December 13, 1881.—Mr. Hyde Clarke, vice-president, in the chair.—The election of Mrs. C. Hancock was announced.—The discussion on the Rev. R. H. Codrington's paper on the affinity of the Melanesian, Malay, and Polynesian languages was continued by Mr. A. H. Keane and Mr. Hyde Clarke.—Mr. M. J. Walhouse read a paper on some vestiges of girl-sacrifices, jar-burial, and contracted interments in India and the East. The great megalithic forms of interment, consisting of Kistvaens, or sepulchral underground chambers, formed of four huge slabs, covered with an immense capstone, and surrounded by a circle of standing stones, abound in nearly all the provinces of the Madras Presidency; but beside these there is another description of burial peculiar to the region of the western coast from Malabar to Cape Comorin. This consists of huge mortuary jars or urns, pear shaped, usually about five feet high by four feet in girth round the shoulders, and tapering to a point at bottom. They are of coarse, thick, red ware, wide-mouthed, generally with a rude incised cross-pattern round their neck. These great urns are buried upright in the ground, not in any cist or chamber, and a large flat stone or slab is laid over them, but no circle of stones ever placed around. They are filled with earth, and contain at the bottom a quantity of bones broken small, some pieces of iron, and occasionally a small urn also filled with bits of bone; or sometimes with clean sand, red or white, which must have been brought from a distance.—Mr. G. Bertin read a paper on the origin and primitive home of the Semites, which was followed by a discussion.

Entomological Society, December 7.—Mr. H. T. Stainton, President, F.R.S., in the chair.—Mr. A. J. Scollick was elected a Member.—Exhibitions: A variety of *Ennomos tiliaria*, Borkh., by Mr. W. E. Boyd.—Bred specimens of *Scenopinus fenestralis*, Latr., *Phora rufipes*, Meig., and *Oscinis pusilla*, Latr., by Mr. C. O. Waterhouse.—A larva of an undetermined species of ant-lion, from Zante, by Mr. F. P. Pascoe. A Curculionideous larva, found feeding in the bulbs of lilies, probably from Japan, by Mr. R. McLachlan.—A specimen of *Harpalus cupreus*, Dej., from the Isle of Wight, by Mr. A. S. Olliff.—A supposed new species of *Telephorus*, from West Wickham, by Mr. H. B. Pim.—Communications: a box of locust egg-cases, with specimens of the Bombyliid larva found feeding on the eggs, transmitted by Sir Robert Biddulph from Cyprus, was exhibited by the Secretary, who read a communication received therewith from the Colonial Office, and the report of the Committee appointed by the Society to investigate the subject.—Sir S. S. Saunders read some remarks received from M. E. André, relative to a species of *Scleroderma*.—Mr. C. O. Waterhouse read remarks on the types of *Cynips psenes* and *C. sycomori*, in the Linnean collection.—Mr. W. L. Distant read descriptions of new species belonging to the Homopterous family *Cicadidæ*; and Mr. A. G. Butler communicated a list of heterocerous *Lepidoptera* collected in Chili by Mr. T. Edwards; Part i., Sphinges and Bombyces.

VIENNA

Imperial Academy of Sciences, December 9, 1881.—V Burg in the chair.—The following papers were read:—Ed. Neusser, a contribution to the knowledge of the colouring-matters of urine.—Bohuslav Branner (Manchester), contribution to the knowledge of cerium metals.—N. v. Lorenz, on the action of metallic lead on an aqueous solution of nitrate of lead.—Willibald Vinier, a sealed packet without inscription.—G. Tschermak, on a previously unobserved case of hemhedry of fesseral system.—E. Weiss and T. Palisa, computation of the elements and ephemeris of the comets probably discovered by Mr. Wendell of Harvard College at Cambridge (Mass.).—W. Tinter, on the error made on putting the cross-wires into the plane of image.

December 15, 1881.—L. T. Fitzinger in the chair.—The following papers were read.—L. Boltzmann, on the theory of the viscosity of gases (part 3).—Some experiments made on the impact of cylinders, by the same.—Fr. Brauer, on the Diptera of the Imperial Museum at Vienna.—A. v. Heider, on the genus *Cladocera*, Ehrenberg.—T. Gaunersdorfer, contributions [to a knowledge of the nature of the *heart-wood*.—O. Tumlirz, on the flow of an incompressiole liquid through pipes of circular section and of any one shape and situation.—On the rotatory movement of a homogeneous liquid around an axis by influence of friction, by the same.—Bela Haller, on the anatomy of the nervous system of the *Muricida*.—T. V. Rohon, researches on *Amphioxus lanceolatus*.—F. Lorenz, on the skeletons of *Stringops habroptilus* and *Nestor notabilis*.—L. v. Barth and M. Kretschy, on the *Pirotoxin* question.—Sig. Freud, on the structure of nerve-cells of the crayfish.—T. Liznar, on the results of magnetic measurements made in Moravia and Silesia.

PARIS

Academy of Sciences, December 12, 1881.—M. Daubrée in the chair.—The following papers were read:—Surveys and itineraries executed in Tunis, by M. Verrier.—Experiments on the rapidity of absorption of virus at the surface of wounds, by M. Davaine. Small portions of the skin of rabbits were cut out with scissors, and fresh virulent anthracic blood was spread on the wound. After one hour or more, the wound was deeply cauterised. Two-thirds of the animals were preserved (a result quite different from those of Renault and M. Colin, who inoculated animals after making a small sub-epidermic incision, and found cauterisation unavailing. An explanation is offered).—On groups of binary forms having the same Jacobian, by M. Stephanos.—Researches with a view to discover organisms parasitic on phylloxera, by M. Gayon. He found microscopic organisms in a small percentage of phylloxeras examined, and tried to cultivate them. Chicken-broth neutralised with potash, and having a phylloxera (first scorched in flame), or some liquid from its body, put into it, soon swarmed with agile rods (bacteria or vibrions), but the author is not sure that the alterative germs were always from the insects (the development being constant). A curious green crystal-yielding product of those microbes, is noted. M. Gayon, is pursuing his studies.—On equations of the form $\Sigma \int_a^b e^{-zx} F(z)dx = 0$, by M. Laguerre.—On a series of Abel, by M. Halphen.—Remarks on the introduction of continuous functions not having a derivative, into the elements of mechanics, by MM. Appell and Jannand.—On a class of functions analogous to Θ functions, by Mr. Elliott.—On international polar expeditions, by M. Mascart. The object is to study, not the formation and course of cyclones, but terrestrial magnetism and allied phenomena; and in this respect the importance of polar stations is indubitable.—On the methods of comparison of induction coefficients, by M. Brillouin.—On the specific heats of gases at high temperatures, by MM. Mallard and Le Chatellier. They find the mean specific heat of carbonic acid, at constant volume, between 1800° and 0° (referred to the equivalent 44), to be represented by 12·6. It increases

continuously up to 2000°, but the rate of increase diminishes with removal from 0°. The formula gives a maximum of 13·7 at 2160°. The specific heats of hydrogen, nitrogen, oxygen, and carbonic oxide, which are equal at 0°, are still so at temperatures exceeding 2000°. The mean specific heat of aqueous vapour, referred to the equivalent 18, is about 11·5 at 1600°.—On the solubility of sulphate of baryta and strontium in concentrated sulphuric acid, by MM. Narenne and Pauleau.—Processes of direct coppering of cast-iron, iron, and steel, by M. Weil. Three are described. The injurious and dear cyanides are replaced by organic acids, or by glycerine.—Pocket-battery with articulated elements, by M. Pulvermacher.—On the decomposition of water by electric effluves in presence of nitrogen, by MM. Deherain and Maquenne. The effluve of high tension causes direct combination of the nitrogen with the elements of the water, producing nitrite of ammonia. This effluve was also proved capable (like that of weak tension) of causing fixation of nitrogen in organic matters.—On the decomposition of metallic formiates in presence of water; production of some crystalline mineral species, by M. Riban.—On the influence of the choroid on acuteness of vision, by M. Fano. He describes observations of the vision of persons having choroidian atrophy.—On tetronerythrine in the animal kingdom, and its physiological *rôle*, by M. de Merejkowski.—On the origin of spermatozoids in hydrozoa, by M. de Varenne.—Note on some points still obscure in the organisation and development of Echinorhynchi, by M. Mégnin. The presence of a bifurcating intestine brings these Helminths towards Trematodes, and removes them from Nematoids.—On the characters presented by speech in deaf-mutes who have learned to articulate sounds, by Prof. Bell.—Observations on the last eruption of Mauna Loa, from November, 1880, to August, 1881, by Mr. Green. He sends and discusses a series of photographs of the lava current, which is the most remarkable that has occurred within fifty years.

December 26, 1881.—M. Wurtz in the chair.—M. Favre presented a fourth and last batch of M. Chasles' scientific MSS. (the total numbering 113).—On some applications of the theory of elliptic functions, by M. Hermite.—Note on the mode of action of soluble ferments, by M. Wurtz. Pepsine and papaine being fixed, in the insoluble state, on certain albuminoid matters, so modify these that they can be hydrated at 40° by action of pure water, forming true peptones.—Classification of fractures of different orders (lithoclases), presented by the earth's crust, by M. Daubrée. Lithoclases are divisible into—I. Leptoclases: small fractures in two directions or one, and either synclases (*interior* mechanical action) or piesoclases (*exterior*); II. Diaclases: fractures often extending, with nearly plane form, more than 100 m. in horizontal or vertical direction. III. Paraclases: like diaclases, but often exceeding 1000 m. in horizontal direction, and presenting great outthrow of indefinite depth. Examples are given in a synoptical table.—Is the ramification in plants everywhere and always acropetal? by M. Trécul. He is led to a negative.—Reply to M. Daubrée's observations in the *séance* of December 19, by M. Blanchard. M. Blanchard had not questioned the existence of an interior sea in the tertiary epoch, about the end of which he had supposed it to disappear, through elevation. Mere isthmuses would have been insufficient for the dissemination which occurred.—Observations on the state of the Mediterranean at the close of the tertiary epoch, by M. Hébert. He gives evidence of an emersion, more or less, at the end of the miocene, and at the end of the pliocene In pliocene time (he thinks) the bottom had not the great inequalities observed now, these being due to dislocations in the quaternary epoch. On the successive differences of observations, by M. Bréger.—M. Malligand indicated the service rendered by his ebullioscope (for determination of alcohol in wines), which the French Syndical Chambers adopted in 1878.—Elements and ephemerides of the comet *g* 1881 (Swift), by M. Bigourdan.—On the successive differentials of functions of several independent variables, by M. Darboux.—On some examples of reduction of Abelian integrals to elliptic integrals, by M. Picard.—Note on naval tactics calculated by Lieutenants Des Portes and Aubert, under direction of Capt. Trève, by M. Trève.—On the works of the Swiss Seismological Commission, and on earthquakes recently experienced in Savoie, by M. Soret. A peculiar feature of some earthquakes, originating south-east of the Lake of Geneva, is that they had a strong effect on the north side of the lake, but were hardly felt on the south side, though this was nearer the place of origin.—On the function which expresses the gaseous state, and on the function λ, such that $\frac{dQ}{\lambda}$ is an exact differential, by M. Gouilly.—Contractions and dilatations produced by electric tensions in hemihedral crystals with inclined faces, by MM. Jacques and Pierre Curie. Between two bronze plates were secured two systems, the lower (to measure variations of pressure) formed of three large thin quartz plates separated by metallic plates, which were connected with an electrometer; the higher, of three large hemihedral crystals, separated by two copper rundles, on one of which were applied two bases positive by pressure, on the other two negative bases The two exterior bases communicated with earth; the two copper rundles with a Holtz machine. The dilatation of the upper system compressed the lower, and the electrometer was affected. The phenomenon was of the same order of magnitude as theory indicated.—On the decomposition of some metallic acetates in presence of water; production of crystalline mineral species, by M. Riban.—Influence of heat and proportions of glycerine on the decomposition of oxalic acid, by Mr. Lorin. The etherification of formic and oxalic acids is, in this class of experiments, a secondary accident.—On essence of angelica, by M. Naudin.—Method of purifying arsenious coppers, by M. Garnier.—Experimental researches proving that various causes, but especially lesions of the brain, may produce, after death, a general or local contraction, by M. Brown-Séquard.—On the mechanism of motor-troubles produced by excitations or lesions of the circumvolutions of the brain, by M. Conty. The circumvolutions do not seem to have any direct relation to the muscles; it is the spinal cord that plays the predominant *rôle* of centre of reaction and transformation.—On the excretion of uric acid in birds, by M. Cazeneuve. Experimenting with sparrow-hawks, he proved that the stimulation or diminution of combustion does not alter the ratio of the principles excreted. The totality of elements increases or diminishes with the quantity of food ingested; which depends on the stimulant or depressive conditions of the medium.—On the *Gastornis Edwardsii* and the *Remiornis Heberti* of the Lower Eocene of the environs of Rheims, by M. Lemoine.—Do the inferior Crustaceans distinguish colours? by M. de Merejowsky. They distinguish quantity, but not quality, of light.—Prolongation of the vegetative activity of chlorophyllian cells under the influence of a parasite, by M. Cornu. He mentions several cases of analogy to the state of lichens (which have vigorous life, though now understood to consist of an alga and a parasitic champignon).—On Sphenozamites, by M. Renault.—On the supposed organisms of meteorites, by M. Vogt. He controverts this theory of M. Hahn, and argues that the structures are inorganic.

CLERK MAXWELL'S "ELECTRICITY AND MAGNETISM"

A Treatise on Electricity and Magnetism. By James Clerk Maxwell. Second Edition. (Oxford: At the Clarendon Press, 1881.)

An Elementary Treatise on Electricity. By James Clerk Maxwell. Edited by William Garnett, M.A. (Oxford: At the Clarendon Press, 1881.)

THESE volumes have a melancholy interest for the student of electrical science, inasmuch as they are the unfinished work of one of its great masters. The printing of the second edition of the larger work had reached the second half of the first volume when it was interrupted by the premature death of the author. Up to this point considerable modifications have been introduced into the work; but the rest is merely a reprint under the superintendence of Mr. W. D. Niven, of Trinity College, Cambridge.

We shall allude by and by to these alterations in the earlier part of the new edition; but it may not be without interest to the readers of NATURE briefly to review the progress of electrical science during the eight years that have elapsed since the publication of the first edition, and to trace the influence of the work therein.

Clerk Maxwell appeared avowedly as the mathematical expositor of Faraday; in this he was the pupil and follower of Sir William Thomson. The electrical papers of the last, reprinted the year before Maxwell's work appeared, reach some of them as far back as 1842; and in the earliest of them he occupies himself with the translation of Faraday's ideas into the ordinary language of Mathematical Physics. He shows that his translation leads to a theory in no wise contradictory of the received theory of action at a distance, so far at least as this theory merely exhibits the facts of observation; but to a theory in some respects more comprehensive, inasmuch as certain experimental facts find a much more natural explanation in it than in the older and more prevalent one. It may be asserted, without fear of contradiction, that Sir William Thomson was the first who thoroughly understood and clearly expounded Faraday. Abroad his methods and conceptions were decried as vague and, although suggestive and worthy of notice, as the machinery that had been used by a man of genius, yet devoid of accurate foundation.[1] At home the loose way in which Faraday's methods and terms had been used, or more properly speaking, abused by many, gave but too specious a confirmation of the justice of this criticism.

What Thomson began Maxwell continued, and in a sense completed. In his work we have the first systematic exposition of Faraday's theory of a dielectric medium applied to all the main phenomena of electricity.

He shows, for the first time, that all the ordinary phenomena of electrical action and reaction can be explained by the thoroughly legitimate physical hypothesis of *stresses* in the medium of having a static or a kinetic origin, as the case may be.

Had this innovation been a mere matter of the transformation of surface into volume integrals (as may still seem perhaps to some who are mathematicians by birth, and physicists by application only), it would not be necessary to dwell on it in these pages. But it was far more. To the old theory of action at a distance, in so far as it assigned the mathematical laws of certain of the observed facts, there could be no sort of objection. Its success in this respect is scarcely rivalled by that of the corresponding artifice in celestial dynamics.

But the theory of action at a distance was not, and never could be, a dynamical explanation of electrical phenomena. It may be true that we know little of what occurs in the medium between electrified conductors; but we are not likely to extend our knowledge by adopting a theory which begins by directing us to divert our attention altogether from the very field in which a dynamical explanation *must* be sought. This strong argument against it is supported by the still stronger, that, notwithstanding the admirable accuracy with which the old theory explains a large body of facts, there are still other facts, continually increasing in number, of which it gives no explanation whatever, if indeed they do not flatly contradict it.

The medium theory was therefore a first and necessary step towards a dynamical theory of electricity. It begins by divesting the facts of all hypothetical raiment, and expressing them in language appropriate to themselves, suggesting nothing but what Nature has indicated, indicating nothing that Nature has denied, supposing as little as may be where nothing has been revealed. Above all banishing from the catalogue of physical conceptions the imponderable electrical fluids that have worked such mischief in indolent minds, and poisoned electrical literature so long.

Moreover the old theory, although it was a weapon of wonderful power in the hands of expert mathematicians, was difficult of translation into even technical verbal expression. It was inflexible and unwieldy when applied in general explanation, and in the universally occurring cases where approximate estimation is all that is necessary or desirable. In one sense therefore Maxwell's treatise was a popularisation of the theory of electricity. By this we do not mean that Faraday's method of lines of force brings the subject to the level of a mind untrained in the handling of accurate ideas, but simply that it often renders the profound and laboriously acquired skill of the mathematical expert unnecessary. In the highest sense, viz. that of an accurate thinker, Faraday himself was, as has been often said, a great mathematician; although he was so little of a mathematical expert, that he once expresses his obligation to one who had calculated the tangents of some galvanometer deflections for him. And yet complaints have often been made of the obscurity of Clerk Maxwell's work. Certainly it is not easy reading; but the difficulties are always to be found where Nature has herself set them; they arise simply because the author refuses to put a bridge over the gap presented by experience. Such complaints come alike from the mathematician in search of an ideal logical completeness, and ever impatient of *facts* that do not fit with his preconception; and from

[1] If the reader wishes to see how much Maxwell's work has done to popularise Faraday's ideas abroad let him consult the electrical papers that have appeared of recent years in *Wiedemann's Annalen*, or read the emphatic testimony of Helmholtz, given at the commencement of the Faraday lecture. See Jour. Chem. Soc., June, 1881.

those whose powers of generalisation do not carry them far enough to put them above regarding the small details of experiment as the ultimate end of science. For both classes there are lessons in Maxwell's pages.

Another most important feature of the work under review is that it is in the strictest sense a Treatise on Electrical *Measurement*. It looks at electrical actions almost exclusively as measurable; it does not profess to be a complete experimental treatise of all electrical phenomena qualitatively or quantitatively observed. In this respect it is a continuation of the labours of its author in conjunction with the rest of the distinguished band of electricians who formed the Committee of the British Association on Electrical Measurements. Maxwell's work is in many parts, particularly in the second volume, a development of the methods employed by this Committee. Many of the electrical measurements there described had, when the volumes were first published, been actually carried out only by the author himself or by very few beside; but now the great majority of them have become the commonplaces of a physical laboratory.

The effect on practice of the work thus consummated in Maxwell's Treatise has been, both directly and indirectly, enormous. The extension of technical applications has been immensely facilitated by the introduction of definite units. Instead of the old vague, unscientific, and still more, unbusinesslike statements of quantity and intensity, we have the precise ideas of electromotive force, resistance, current, and so on, measured in their respective units, the volt, the ohm, the ampère, &c.; and now electrical commodities can be bought and sold by rule and measure, as heretofore cloth, coals, or horse-power. And yet we have noticed a tendency now and then in technical journals, on the part of men of practice, evidently ignorant of the history of the science they apply, to depreciate unduly the services of their theoretical brethren. One would have thought that in electrical science, beyond all others, where the mutual obligation is so great and so equally balanced, the folly of either the man of theory or the man of practice attempting to minimise the services of his fellow worker would have been evident.

The seal has been set to the work of the B.A. Committee by the Congress of Electricians which met last autumn in Paris, by the adoption of the B.A. units as the basis of an international system. To this result Maxwell's treatise has powerfully contributed, but it would be little in the spirit of its author to boast of this as a national, much less as his personal triumph; it is more fitting to remind the readers of NATURE that in the work thus consummated the English electricians were the followers of Gauss and Weber, and, more remotely, the disciples of Coulomb, Poisson and Ampère, so that they have simply acted up to the motto of all true scientific men, λαμπάδια ἔχαντες διαδώσουσιν ἀλλήλοις; they have but passed the torch from hand to hand.

The electromagnetic theory of light formed a fitting crown to the first edition of Maxwell's Electricity. It was left by its author in the form of a general sketch, carried just so far as was necessary for comparison with experiment. Concerning the progress of this theory during the last eight years much might be said, and it is greatly to be regretted that we have not before us what Maxwell himself would undoubtedly have said, had he lived to superintend the publication of the second volume of his work. It has formed the basis, as every good physical theory should, for a large number of further researches, both theoretical and experimental. We need only mention the work of Helmholtz, Boltzmann, Rayleigh, Silow, Hopkinson, Fitzgerald, Glazebrook, J. J. Thomson, and many others. The theory has not proved, and its author certainly never expected it to prove, a framework ready made with appropriated pigeon-holes, into which would naturally fall every electrical fact to be discovered in all time coming; but it has proved itself, so far, the best theory with anything like a physical basis that has been proposed to explain the facts with which it deals. The more it has been worked out, the more it has been found to explain in a natural way the known phenomena of electricity and light; and it does not appear to have been shown as yet that there is any observed fact that may not ultimately be reconciled with it, either by farther development of the theory, or by deeper probing of the experimental results. This is really all that could be expected when we reflect that, much as we know about electricity, there is an infinity yet unknown.

We have now to allude briefly to the changes that have been made in the second edition.

In the introductory chapter we are glad to see that few changes have been made; we need, therefore, only recommend our readers to peruse it again, as perhaps the most admirable thing of the kind that has been written in any language; we direct their attention more particularly to the distinctions drawn between electricity, force, and energy, of which some of our scientific men seem strangely oblivious, and to the admirable remarks on the two fluid theory. We must at the same time warn the student as to a radical change that has been introduced into the terminology of the subject. He is aware that at every point of the electric field there is conceived a directed quantity, which in the former edition of this work was called resultant electric force, or the electromotive force *at the point*, according as it was regarded from the ponderomotive or electromotive point of view, and he is also aware that the electromotive force *at a point* was a very different thing from the electromotive force *between two points*, the latter being in point of fact of different dimensions. It was always difficult, even for those who clearly understood the distinction, to avoid occasionally using the one term where the other was appropriate. Most probably from a feeling of this difficulty, our author has substituted for the two first of these terms *resultant electric intensity and electromotive intensity* respectively, wisely leaving the old established terms *electromotive force between two points* with its original meaning, although in point of fact it involves an abuse of the word *Force*. We could have wished the danger of confusion still more effectively barred by dropping the word "electromotive" in the first case altogether; but a more serious objection to this change is, that the author evidently intended, from his foot-note on p. 72—

> "The electric and magnetic intensity correspond in electricity and magnetism to the intensity of gravity, commonly called g in the theory of heavy bodies,"

to have made a corresponding change of terminology in the case of magnetism; whereas on turning to the second volume we find intensity of magnetisation used in its old

sense, and (resultant) magnetic force used in the sense in which magnetic intensity occurs in the above note, and, what is worse, in place of electric intensity or electromotive intensity we find on, p. 239, "electromotive force," and on p. 244, "electromotive force at a point" used in its place. This result of the interruption of the issue of the new edition is unfortunate, for it renders the confusion of terms greater than ever, and affords a kind of cover to those who excuse or justify the inaccuracy of their own ideas by appealing to the terminological inconsistencies of standard works. Yet we can scarcely blame the editor, for it is a very delicate matter to interfere with another's work, even in points like this.

The want of definiteness in electrical terminology makes itself felt in the definition of the electric strength of a dielectric; thus we find, on p. 51—

"The value of the electromotive force which can exist in a dielectric without a discharge taking place, is called the electric strength of the dielectric."

And again on p. 54:—

"The intensity of the electromotive force when this takes place is a measure of what we may call the electric strength of the dielectric."

Assuming for a moment that any accurate definition of electric strength can be given, which at present, experimentally speaking, is open to doubt; or, which comes to the same thing, taking, as Maxwell probably means us to do, an ideal case, the second of these definitions is right, if we understand by intensity of the electromotive force resultant electric intensity, or electromotive intensity, as previously defined; while the first, strictly read, *i.e.* taking electromotive force to mean the electromotive force between two points, is clearly wrong; for, if it were right, a spark would always pass between two conductors in the same medium when the difference of potential between them is the same, no matter what their form or surroundings, which is well known to be untrue.

In this connection we may mention that the account formerly given of Thomson's classical experiments on the electric strength of air no longer finds a place in Art. 57. No doubt the author had intended to describe them later on along with what has been done of late in the same direction; but no mention of them occurs, except a cursory one in Art. 59; yet we are still referred in Art. 369 to Art. 57 for the account which is no longer there. It is a pity that a footnote was not inserted referring the reader to the reprint of Thomson's papers.

In Chapter II. we may note, as new, an interesting account of Cavendish's experiment, on which, mainly, we may now rest the evidence for the elementary law of electrostatic action; a simplification of the treatment of the variation of the potential at charged surfaces; farther direct application of the theory of lines of force in proving electrical theorems of considerable interest and generality; and a clearer explanation than was formerly given of the distinction between the real electrification according to the medium theory and the apparent electrification which may be used to represent it, if we abstract the specific inductive capacity of the dielectric.

Chapter III. has been in great part rewritten, and several very interesting and practically useful calculations of the approximate values of coefficients of induction and potential have been added. In Chapter IV., which contains the general theory of electrical equilibrium, the changes have been greater still; the result has been, on the whole, we think, considerable simplification; it would appear, however, from the way in which the chapter ends, that the author had contemplated some farther additions. Chapter IX. has also been greatly modified; in particular the problem of two spheres has been worked out in great detail, and series given to a high degree of approximation for the coefficients of induction and potential.

The rest of the work is practically a reprint from the former edition, and calls for little remark. We may, however, call the attention of our readers to Art. 261, the ideas and notation of which will, we believe, be found discordant with the best modern chemical views.[1] The editor has very properly appended a note to Art. 357, calling attention to Mr. Lodge's exposure of the fundamental defect of Mance's method (in the *Philosophical Magazine* for 1877, not 1857, as the reference is printed). Mr. Lodge's remarks are, so far as we know, the first published allusion to the matter, but the defect in question was well known to Prof. Clerk Maxwell, for it was discussed with him by the present writer some time before the above date. It used to be not uncommon to set over-confident students in the Cavendish Laboratory the problem of measuring the internal resistance of a battery, and then to explain to them the reason of the hopelessly indefinite character of the results obtained under certain circumstances by Mance's method. Notwithstanding Mr. Lodge's remarks, one sees, even in the most recent text-books, this method confidently cited as apparently irreproachable.[2] So tenacious is scientific error! Another correction we may mention—the interlacing circuits in Art. 421 *are* now so arranged that the integral $\iint \Pi \, ds \, d\sigma$ vanishes.

Before taking leave of the work, we have to express the gratitude which the scientific public owes to its editor, Mr. Niven. It has been our duty to indicate some points in which there might have been improvement, and we have said little as to what has been actually done by Mr. Niven. It is but justice to him, therefore, to add that we went over the new edition, and compared it with our copy of the first edition, and we found that in almost every case the errors we had noted were corrected, while explanations had been inserted at many of the places where we had found them necessary. The labour involved in doing all this will be best understood by those who are perfectly familiar with the whole of Maxwell's great work, and all such will know how to appreciate the conscientious labour which Mr. Niven has so unostentatiously bestowed on the editing of this edition.

The regret one feels that Prof. Maxwell did not live to complete his work is much increased when we read the elementary treatise. In the earlier parts it is characterised by that originality, freshness, and exemplary clearness familiar to the readers of his Heat. Chapters I. and II. reproduce with more ample experimental detail the admirable introduction to the larger work. Chapter III. gives the mathematical theory of electrical work and energy in a form accessible to students of moderate mathematical acquirements, although such need not expect to

[1] This applies also to the corresponding passage in the elementary work.

[2] It is unfortunate that Mr. Garnett should have transferred the description of Mance's method to the Elementary Treatise, without correcting or alluding to the error it contains.

find it easy reading. Chapter IV., on the exploration of the electric field is perhaps the most interesting in the book; its contents will be familiar to those who heard the lectures of its author, but much of it is new to the scientific public. Chapter V. contains the theory of Faraday's lines of electric induction, and here for the first time the reader begins to feel that the matter must have been left in a state more or less unfit for publication. The text reads more like a series of disjointed notes than a coherent treatise, and the admirable simplicity and symmetry of treatment which characterises the earlier part of the work is lost. Still, what we have is of great interest, and will be invaluable to a good teacher in giving him hints how to arrange an elementary exposition of Faraday's theory. Chapters VI., VII., and VIII. are more complete, and will be very useful in giving to beginners in electricity some idea of the applications of the mathematical theory; Chapter VIII., on capacity, is one likely to be particularly useful, as it deals with one of the fundamental ideas in electrical measurement. We recommend it all the more, as we have seen the term capacity both ill defined and loosely applied in recent treatises. Chapters IX. and X., fragmentary as they are, are full of interest to those who have studied the larger work; for they throw much light upon many points concerning which the author had formerly but briefly indicated his opinion. We may mention more particularly his remarks on the vexed question of contact electromotive force; also, as new, and specially interesting, the experiments on the insulating power of air and other gases, Art. 138, *et seq.*

The rest of the book is a series of extracts from the larger work, concerning the utility of which, in their present form and arrangement, there will be difference of opinion.

In the interest of the author's reputation it might have been better to have published simply what he had left in MSS. in a more confessedly fragmentary form. If, however, the additions that have been made will secure the use of the treatise by elementary teachers, we shall rejoice; for some of the manuals which they use are not remarkable either for scientific method or for the extent and accuracy of their information; in fact the study of many of them, far from introducing the learner to the science of electricity, is simply a waste of his time.

G. CHRYSTAL

OUR BOOK SHELF

The Zoological Record for 1880; being vol. xvii. of the Record of Zoological Literature. Edited by E. C. Rye, F.Z.S. (London: John Van Voorst, 1881.)

WE heartily congratulate the editor on his praiseworthy success in publishing this important Record of Zoological Literature for 1880 before the termination of 1881. It is the first time, as the editor himself reminds us, that this event has taken place since 1870, and now we trust it will be once more the usual plan. So far as we have been able, by looking here and there throughout the volume, to ascertain, this expedition has not been at the expense of accuracy; and as to incompleteness, any omissions are very easily supplied in the next volume. The Recorders are nearly the same as for 1879, Mr. G. A. Boulenger taking the place of the late Mr. O'Shaughnessy, and reporting on the reptiles, batrachians, and fishes. Mr. W. A. Forbes gives us an admirable report on the mammals. This and Mr. Howard Saunders' report on the birds leave little to be desired in either the arrangement of the matter or in the terseness and yet clearness of the notices. The latter Recorder adopts P. L. Sclater's systematic arrangement as laid down in the important paper by Dr. Sclater "On the Present State of the Systema Avium." The mollusca and molluscoida are reported on by Prof. Ed. von Martens, who also gives the record of the crustacea. These we venture to regard as the model reports of the volume. After a pretty full list of the publications relating to the group recorded, we find a list of the special journals and manuals relating to the class. Then under the heading of Anatomy and Physiology, we find most interesting summaries of the additions made to a knowledge of the general morphology, muscular system and movement, shell formation, digestion, excretion and secretion, nervous system, organs of sense, of generation, embryology, abnormities, and even on the action of poisons. After this some details of the geographical distribution, and of the recently-described forms. The amount of labour spent over this most useful grouping of details on the part of the recorder is great, but the reader reaps from it an immense benefit. The literature of the arachnida is recorded by Rev. O. P. Cambridge, with the assistance of Mr. F. M. Campbell. To Mr. Kirby falls the larger share of the Record of the insecta; indeed all the orders save the neuroptera and orthoptera, which fall to Mr. McLachlan's share are reviewed by him. The vermes and echinoderms are recorded by Prof. Bell; the hydrozoa and cœlenterata by Mr. A. G. Bourne; the anthozoa by Mr. S. J. Hickson; while the literature of sponges and protozoa is recorded by Mr. Stuart O. Ridley. From a summary appended by the editor we find that this volume contains a record of no less than 1008 new genera and sub-genera, described as follows:—

Mammalia	34	Myriopoda	2
Aves	16	Insecta	438
Reptilia	21	Vermes	28
Pisces	31	Echinodermata	24
Mollusca and Molluscoida	79	Coelenterata	70
Crustacea	80	Spongiida	51
Arachnida	78	Protozoa	56

a goodly number, going even beyond the average of most years.

Land und Leute in der brasilianischen Provinz Bahia. Streifzuge von Julius Naeher. (Leipsig: Gustav Weigel, 1882.)

THE author essays, in a small volume of not quite 300 pages, to write a Guide to the Province of Bahia. Starting from Hamburg he steamed, *viâ* Lisbon, the Canary and Cape de Verd Islands, to Brazil, and he asserts that he found the steamers on this route excellent. The details of all the other routes from Europe are, however, also given. As the work is the result of the author's own observation, it only describes a small part of the Brazils. It affords a graphic insight into the tropical vegetation of the country, and gives many details as to the sugar plantations. The social life he did not find to differ much from that described in the older books of travel; only the Indians and the wild beasts were less numerous and troublesome. In Bahia about one-fifth of the population belonged to the white race, while about one-half were pure negroes, and the rest were half-castes. While the author does not profess to give a scientific description of the products of this province, he still has evidently paid a good deal of attention to the fruits and other produce of the colony, and in many cases gives statistics as to the present value of these. The gradual abolition of slavery is beginning to hamper the cultivation of sugar, and the great question of the day will no doubt soon be, How is the agriculture of the country, to which so much of the wealth of the country is at present due, to be kept up when slave labour comes to an end?

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A Glimpse through the Corridors of Time

IN a letter which appeared in last week's NATURE (p. 217), Dr. Dupré refers to a "too much forgotten paper by Immanuel Kant," and speaks of Kant's contributions to natural science as being, at present, "almost universally overlooked."

Whatever may be the case elsewhere, I do not think that, in England, we are open to this reproach, inasmuch as in the year 1869, when I had the honour to be President of the Geological Society, a very considerable portion of my anniversary address "On Geological Reform" was devoted to an attempt to do justice to Kant's work, and to indicate the high place which it occupies in the history of scientific geology. The address is reprinted in my "Lay Sermons," and therefore I have reason to know that a considerable proportion of the reading, or at any rate book-buying, public has no excuse for "overlooking Kant's work."

I may remark, in passing, that, so far as my knowledge extends, the extreme "Uniformitarianism" which Prof. Ball attacks, has long been as much "a creed outworn" as "Plutonism" or "Neptunism." Indeed, I said as much in 1869.

Normal School of Science and Royal School of Mines, South Kensington, January 8

Outburst of Sun-Spots, July 25, 1881

MY letter of August 5, 1881, which appeared in NATURE, vol. xxiv. p. 508, stated that a considerable group of sun-spots burst into appearance between 4 and 5 p.m. (about) on July 25, 1881; or more exactly that the new group was absent at 3h. 58m. (*i.e.* in negative No. 1175), but was present at 4h. 47m. (*i.e.* in negative 1176), local apparent time; further, that no additional negatives could be taken here until July 30, when the spots had disappeared.

This communication has elicited obliging notices by other observers, including Prof. Piazzi Smyth and Prof. Perry, F.R.S., in NATURE, besides others posted to me direct. The observers were not able to observe the sun when the outburst occurred, nor for some twenty-two hours afterwards; none of the observers saw the new group.

One of the observers remarks: "I fancy your sudden group of spots is after all a curious system of blemishes in the negative!" Certainly the appearance of the negative (No. 1176) did not (to me) admit of conjectures suggesting the *unreality* of the spots. However, in presence of the remark now offered, I made inquiries of the photographer, Mr. L. H. Clarke, as to the circumstances connected with his detection of the outburst. I inclose his narrative (see below). It establishes the fact that he *first* saw the new spot-group *on the ground-glass slide* used for focussing the photoheliograph, and indeed that it was *this view* of the unexpected event which urged him to persevere (notwithstanding the clouded state of the sky) in securing a negative, *i.e.* No. 1176, on which the new spot-group he had seen on the ground glass slide stands photographed. His narrative further establishes narrower limits of time in which the outburst occurred, *i.e.* between 3h. 58m. to about 4h. 35m., instead of to 4h. 47m. p.m.

I communicate the foregoing facts, as they are essential circumstances of the event, and should be placed on record.

J. B. N. HENNESSEY

Debra Doon, N. W. Provinces, India, December 16, 1881

On July 25, 1881, the sun was quite invisible owing to clouds, until towards 4 p.m., when a temporary break occurred, and I took negative No. 1175 at 3h. 58m. p.m. After this the sun again became invisible, while the rising clouds were so dense as to present little hope of getting another negative; so, as evening was approaching I was thinking of closing work for the day, when, while I was still watching at the instrument, an unexpected opening occurred in the rising clouds below the sun, and, soon after, the sun's image appeared on the ground glass used for focussing. To my surprise I now saw, at about 4h. 35m. p.m., a large group of spots about the sun's centre, which were quite absent in the previous negative, No. 1175; little expecting anything of the kind, or indeed to see the sun at all that evening, I was not ready to expose a plate, but now seeing what had happened, I determined to persevere, though the clouds were very unpromising of another break. So I at once took points on my blue setting glass, as is usual to set the instrument by (so as to avoid needless hiding of spots behind the wires), and having done this, I prepared a plate as quickly as possible, and set the exposing slide all ready, though the sun now was invisible; fortunately another opening occurred at 4h. 47m. p.m., when I took negative number 1176, in which appears the group of new spots about the sun's centre, which new group I saw without doubt at about 4h. 35m. on the ground glass for focussing. I then continued to watch for another negative until 5h. 30m. p.m., when the sky having become quite dark, I gave up work for the day.

Polymorphism of the Flower-heads of Centaurea Jacea

IN *Centaurea Jacea*, the flower-heads of the same stem, as far as I have seen, are always of the same form, but different stems of the same locality often present astonishing difference in their flower-heads.

In the most common and apparently original form the flower-heads consist of florets which are all of the same tubular shape and all contain both fully developed anthers and stigma, the divergence of the outer florets giving to the whole head a diameter of 20–30 mm. (see H. Müller, "Bie Befruchtung der Blumen," p. 382–384). From this original form variation has gone on in two opposite directions, the final effects of this variation being on the one side most conspicuous male flower-heads of 50–55 mm. diameter, and on the other side less conspicuous female flower-heads of 30–35 mm. diameter. In both these extreme forms the outer row of florets possesses greatly enlarged radiating corollas which are sexually functionless, but useful in making the flower-mass more conspicuous. In the male flower-heads anthers and pistils of the disk-flowers are well-developed, but the style-branches never open so as to expose their stigmatic surfaces, and in their basal portion are grown together. In the female flower-heads, on the contrary, only the pistil of the disk-flowers is fully developed, the anthers being pollenless, shrivelled, and brownish-coloured.

These two extreme forms are linked with the original one by a continuous series of gradations. When in the original form variation begins in the one direction, the outer row of florets gradually becomes longer and more radiating, and in the same degree their sexual organs diminish in size and become functionless, the anthers first aborting, and then the pistil. Finally, the barren ray-florets continuing to increase, the pistils of the disk-florets, too, become functionless, and the conspicuous male flower-head is accomplished.

In the contrary variation some of the outer florets of the original form begin to diminish in size, while their anthers become brownish and pollenless, and this change step by step proceeds inwards and seizes a greater and greater number of disk-florets, until the whole flower-head is female, and reduced to a diameter of 15–18 mm. This state being reached, the corollas of the marginal flowers recommence to increase and become radiating, while in the same time their anthers disappear without leaving any trace, and their style-branches remain closing together.

These are, shortly sketched, the main varieties of *Centaurea Jacea*, near Lippstadt. Further details are about to be published in one of the next numbers of *Kosmos*.

Lippstadt HERMANN MÜLLER

The Weather

THIS morning I noticed the first blossoms of the Colt's-foot (*Tussilago farfara*), ordinarily considered an indication of the near approach of spring. For many years a generous rivalry has existed between myself and a friend (both travellers on the

North Kent Railway, on the banks of which the plant is excessively abundant) as to which could record the first blossoms. I think I have seen them as early as the first week in February; on the other hand, it is possible that the first week in April is on record as the earliest appearance; almost without exception it truly indicated that any long period of severe weather was over for that winter. Will this prove the case with the so-called "winter" of 1881-1882?

Indian Fossils.—Dr. Gordon, of the Manse, Birnie, Elgin, writes that there is a pretty large collection of Siwalik fossils in the Falconer Museum at Forres, N.B.

THE TRANSIT OF VENUS IN 1882

THE French Ministry of Public Instruction has issued the *Procès-verbaux* of the International Conference on the approaching Transit of Venus, held at Paris from the 5th to the 13th of October last. Representatives of fourteen nationalities were present at the Conference, but regret was expressed that the United States had no delegate present Russia; also was unrepresented, but it has been understood that the Government of that country do not propose to organise expeditions beyond the limits of the Empire, or perhaps to undertake observations elsewhere than at the fixed observatories. M. Jules Ferry, then Minister of Public Instruction and the Fine Arts, was present at the opening meeting of the Conference on October 5, and stated its objects; he was named honorary president by acclamation, and on his proposition the meeting proceeded to the election of the acting-officers, which resulted in the choice of M. Dumas, perpetual secretary of the Academy of Sciences of Paris, as president; Prof. Fœrster, director of the Observatory of Berlin, and Prof. Weiss, director of the Observatory of Vienna, as vice-presidents; with M. Hirsch, of the Observatory of Neuchâtel, delegate from the Swiss Republic, and M. Tisserand, the proposed chief of a French expedition to Martinique, as secretaries. M. Dumas pointed out that the expeditions in 1874 were organised by the various nations without any general previous understanding, each acting independently, adding that the necessity of cooperation in the arrangements of different countries for the observation of the approaching phenomenon is now generally admitted. He directed special attention to the desirability of coming to some definite conclusion as to the employment or otherwise of photography on the occasion. In the discussion which followed Prof. Fœrster announced that the German Commission had resolved not to employ photography in 1882, and Mr. E. J. Stone, the Radcliffe Observer, directing astronomer of the British Commission, which he represented at the Conference, mentioned that it was not seriously intended to introduce photography in the expeditions of 1882, remarking that the French results from this method were not encouraging, and the American results had not been published in time to allow of due discussion before the British Commission was called upon to advise the Government on the best methods of observing the transit.

M. d'Abbadie, however, reminded the Conference that good results had been obtained by Mr. Todd from the American photographs. M. Hirsch said the scientific public had been surprised to find that after the lapse of seven years since the transit of 1874 there was yet but a partial publication of results, and these in small number: each nation had given its solar parallax, but could not a different method of procedure be adopted for the transit of 1882? It might be worth while to form a *bureau des calculs*, charged to collect, reduce, and discuss the whole of the observations in 1882, and the same bureau might also discuss the entire series of observations at the late transit, and publish the final value of the sun's parallax from the two transits. Prof. Fœrster took a similar view; Prof. Oudemanns preferred that each commission should in the first place draw up and publish its separate report; the definitive parallax would follow. At the second sitting of the Conference on October 6 M. Dumas notified the stations selected by the French Commission and the observers whom it was proposed to place in charge of the respective expeditions. At three of the stations, viz., Santa-Cruz, Rio Negro, and Port-Desire or Chubut, in Patagonia, M. Mansilla from the Argentine Republic, said the French expeditions might count upon the co-operation of his Government, and the same was stated as regards Santiago, another of the French stations, by Dr. Moesta on the part of the Government of Chile. M. Liais, delegate from Brazil, mentioned that M. Cruls would observe at Rio Janeiro, where the sun would be nearly in the zenith soon after the second contact; he had also organised a station in a locality situated at an altitude of 1800 metres to guard against unfavourable weather at Rio, and a third station would be at Pernambuco, where the chances of a clear sky are very great; further, M. Liais contemplated two additional stations, one of them in the Straits of Magellan; the telescopes employed in Brazil would be of 9 inches and 6 inches aperture. Prof. Fœrster stated that the German Government had not finally decided upon the precise localities to which the four authorised expeditions would be sent, but it had been proposed to place two of them in the southern part of the United States, one in the south of the Argentine Republic, and the fourth at the Falkland Islands. With regard to observations in the Straits of Magellan, M. Bouquet de la Grye, of the French Navy, said the Chilian Government had for a long time past instituted meteorological observations which, while they indicated that the probabilities of a fine sky were great at Santiago, were not promising for the Straits: "Il n'y a peut-être pas une probabilité de $\frac{1}{10}$ de voir une partie seulement du phénomène." Prof. Fœrster stated that according to his information, there existed near the Magellan Straits very limited localities where the conditions would be favourable in December. With regard to the Antilles, to which expeditions were intended to be sent, the conditions, according to M. Bouquet de la Grye, were complicated: at Martinique they would be pretty good, as also for Florida; at Cuba moderately so; on the coasts of the Gulf of Mexico the chances of fine weather are small, though improving in the interior. M. Pechüle of Copenhagen said the Danish Government proposed, with the assent of the Chambers, to equip an expedition either to St. Croix or St. Thomas. Dr. Bakhuysen said, although the Netherlands Government had not made a final decision, it was proposed to send an expedition to Curaçao or St. Martin in the Antilles, and a heliometer would form part of the equipment. M. Viegas, delegate from Portugal, remarking that the weather is usually magnificent in December n that country, mentioned that the observatories of Lisbon and Coimbra possessed large equatorial instruments, and suggested, if it were considered of utility, an expedition might be placed in the Portuguese colonies, at Benguela, for example. Mr. Stone reported upon the selection of stations by the English Commission, the principal centres being the Cape, Australia, New Zealand, and the Antilles. On the part of the Spanish Government, M. Pujazon, director of the Naval Observatory at San Fernando, said it was intended to organise two stations, one at Porto Rico, the other in the southern part of Cuba, where the chances of favourable weather will be considerable: equatorials of 6-inches (English) aperture to be supplied. At the same sitting of the Conference, M. Dumas proposed the nomination of two committees, the one to be charged with the distribution of the observing-stations, the other with the methods and instruments of observation; it had been previously pointed out by M. d'Abbadie that he was named to conduct an expedition to Cuba on the part of the French Government, where it was now

stated one would also be sent by Spain: the duplication of stations is not desirable in such a case. The President's propositions were adopted, but in addition the Committee on Methods was also charged with the consideration of the calculations and publication of the observations in 1882, and were further deputed to consider the formation of a temporary international bureau, to be intrusted with the reduction of the whole of the observations. At the fifth and last sitting of the Conference on October 13, the report from the Committee on Methods of Observation, &c., was presented. The proposals of the British Commission respecting the phenomena to be noted at the contacts of the limbs of the sun and Venus, brought forward by Mr. Stone, were made the foundation for a series of instructions to observers, some explanations being appended thereto. After much divergence of opinion with regard to the advantage of an international *bureau des calculs*, the following proposition introduced by M. Dumas, and supported by Mr. Stone on the part of the English commission, was adopted by a large majority.

"The Conference expresses the wish that the French Government may be willing to communicate in diplomatic form with the other governments represented in this conference, or those who are interested in the transits of Venus, in order to lay before them the proposition of convoking, after the return of the expeditions of 1882, an international conference on the transits of Venus, with a view to establish an understanding on the means to be adopted to arrive at the best and most expeditious use of the observations of the transits of 1874 and 1882, and in particular to inquire whether towards this end a temporary international bureau should not be formed."

The report closes with a list of the projected stations for the expeditions, so far as at present arranged. The British stations selected are:—Bermuda, Jamaica, Barbados, Cape Colony (3), Madagascar, New Zealand, Falkland Islands (?), with the Australian observatories.

ON THE PHYSICAL CAUSE OF THE OCEAN BASINS

GEOLOGISTS have reason to thank Prof. Ball for directing their attention to the remarkable investigations of Mr. G. H. Darwin upon "The Precession of a Viscous Spheroid, and the Remote History of the Earth," (*Phil. Trans.* Roy. Soc., Part ii., 1879). Prof. Hull has already been led to point out one result which appeared to him to flow from them, in showing how the ancient tides may have produced the planes of marine denudation, though Mr. Darwin has since expressed doubts as to the legitimacy of this conclusion. I wish to offer another speculation arising from Mr. Darwin's work, which I think may account for the hitherto unexplained distribution of land and water upon the surface of the globe.

Herschel remarked long ago, in his "Physical Geography," that the prevalence of land and water over two opposite hemispheres "proves that the force by which the continents are sustained is one of *tumefaction*, inasmuch as it indicates a situation of the centre of gravity of the total mass of the earth somewhat eccentric relatively to that of the general figure of the external surface —the eccentricity lying in the direction of our antipodes: and is therefore a proof of the comparative *lightness* of the materials of the terrestrial hemisphere." In my "Physics of the Earth's Crust," just published, I have shown reasons for thinking that the distribution of the materials of the earth, which gives rise to this condition, is of the following kind. I accept on the whole the theory that the earth is a hot globe, of which the superficial crust is rendered solid by having become cool, and that the central part is solid, either from great pressure, or from whatever other cause may be assigned; an intervening layer beneath the cooled crust still remaining liquid. The layers of which the whole is composed are arranged in order of their density. Now I have given reasons for believing that Herschel's "comparative lightness of the materials of the terrestrial hemisphere" arises from the fact that the cooled crust beneath the continents is intrinsically less dense than that beneath the great oceans. I think that the crust beneath the continents consists of the cooled acid, or granitic, and therefore lighter magma, which ought naturally to have formed originally the entire superficial portion of the globe. But I conclude that the bottoms of the great oceans consist nevertheless of a crust formed out of the cooled basic layer. Beneath the cooled crust the laws of hydrostatic equilibrium would require that, if the substratum is truly liquid, it should be of the same density under both these areas. I also conclude that the upper surface of the basic crust which forms the floor of the oceans is really depressed below the mean surface of figure.

To these conclusions I arrived without being able to suggest any satisfactory explanation of the facts. I saw that they agreed with, and were supported by, the view of those geologists who assert that the great oceanic and continental areas have never changed places; but neither could I any better see the reason for this.

Let us now inquire whether Mr. Darwin's researches throw any light upon the subject. I shall refer chiefly to the summary and discussion of results appended to his paper, for it is small blame to a sexagenarian, not a professed mathematician, to admit that to follow the *calculations* is beyond the scope of his powers. As I understand Mr. Darwin, he thinks it probable that the moon and the earth were once a single mass, and that at the time when this mass was rotating at the rate of about one revolution in five hours the whole separated into two portions, the smaller of which went to form the moon; and that the moon then began to recede from the earth, until now, after the lapse of fifty-four millions of years *or more*, it is at its present distance. The ellipticity of the mass when rotating at the above-named speed would be about 1-12th. [This would make the mass very much less compressed than an ordinary orange.] He does not think it probable that this amount of ellipticity would cause the spheroid to break up simply from the centrifugal effect of the rotation; but he suggests, judging from the calculated period of a gravitational oscillation of a fluid spheroid, of uniform density equal to the mean of the earth, viz. 1 hour 34 minutes, that the period of the free oscillation of a spheroid "consisting of a denser nucleus and a rarer surface," but of the same mean density as the earth, might coincide with the period of the bodily solar tide at that time. "It seems to be quite possible that two complete gravitational oscillations of the earth in its primitive state might occupy four or five hours." "Accordingly the solar tides would be of enormous height." He then adds: "Does it not then seem possible that, if the rotation were fast enough to bring the spheroid into anything near the unstable condition, then the large solar tides might rupture the body into two or more parts? In this case one would conjecture that it would not be a ring that would detach itself."

I now proceed to build my speculation upon his. It is obvious that, according to the above theory, the act of fissiparturition by which the moon was born must have been sudden. One of the two solar tidal protuberances broke away from the earth to inchoate a separate existence. A great but shallow hole must consequently have been formed, whose centre would have been on or near the equator. Prof. Ball says: "Not for long would that fragment retain an irregular form; the mutual attraction of the particles would draw the mass together. By the same gentle ministrations the wound on the earth would soon be healed. In the lapse of time the earth would become as whole as ever, and at last it would not retain even a scar to testify to the mighty catastrophe."

I form a less hopeful prognostication. I think the ocean basins are the scar, which still testify to the place of separation.

The density of the moon is 0·56654 times that of the earth. Putting the mean density of the earth at 5·5, this makes the density of the moon 3·1. The density of granite is about 2·68, and that of basalt 2·96. Consequently the density of the moon is a little greater than that of the basic layer of the earth's surface, which I think we may expect to occur at the sea-board at a depth of about 25 miles. The entire mass of the moon is 0·011364 of the mass of the earth.

Accordingly, it would require a layer of about 31 miles thick, of the density of granite, to be taken off the surface of the primitive mass to make a body of the mass of the moon; and if the mean density of the matter removed was the same as that of the moon, a somewhat thinner layer would suffice. But if we reduce the area of the skin removed to the area of the oceans, it would require to be $\frac{197}{146} \times 31$, or about 41 miles deep. Hence a uniform layer rather less than 41 miles thick taken off the oceanic areas would be sufficient to make the moon.

Of course the layer removed would not, in fact, have been of uniform thickness. But the above estimate gives an idea of the size of the cavity which would be produced. What then would happen? This would depend upon whether the surface had already become at all solid. I conceive this would be the case at a very early stage, judging from the manner in which a solid layer forms on the liquid lava of Kilauea. The hole would therefore fill up by the rise of the liquid from below, rather than by the lateral approach of the edges of the wound. When the raw surface again solidified we should have a crust of greater density over the area in question, because formed from a lower and denser layer, which would have risen not quite to the level of the lighter crust. There would, however, have necessarily been a certain amount of flow in the upper fluid layers towards the cavity, and this would have carried the cooled granitic crust which, floating on it, still remained upon the earth along with it. What was left of the granitic crust would therefore be broken up into fragmentary areas, now represented by the continents. This would make the Atlantic a great rent, and explain the rude parallelism which exists between the contours of America and the Old World.

The sudden rupture of so considerable a fragment from the rotating spheroid, would alter its mass, form, and moment of momentum. It appears then that its axis of rotation would be altered, which might account for the fact, that the approximate pole of the oceanic area is not in the equator.

The volcanic surface of the moon, if volcanic it be, would lend considerable support to the view which I maintain, that the water substance emitted by volcanoes is an integral constituent of the fluid substratum. For when the moon broke away from the earth it would carry with it the aqueous constituent of the magma. Owing to the much smaller force of gravity in the moon, the pressure under which this would there be placed would be much less than in the earth. Consequently it would more easily escape, and the signs of volcanic action would be more pronounced. But the difficulties surrounding terrestrial vulcanism are so great, that one is hardly tempted to add the lunar to them. O. FISHER

CLASSIFICATION OF THE DINOSAURIA[1]

IN the May number of the *American Journal of Science* (p. 423) I presented an outline of a classification of the Jurassic Dinosaurian reptiles of this country which I had personally examined. The series then investigated is deposited in the Museum of Yale College, and consists of several hundred individuals, many of them well preserved, and representing numerous genera and species. To ascertain how far the classification proposed would apply to the material gathered from wider fields, I have since examined various Dinosaurian remains from other formations of this country, and likewise during the past summer have visited most of the museums of Europe that contain important specimens of this group. Although the investigation is not yet completed, I have thought the results already attained of sufficient interest to present to the Academy at this time.

In previous classifications, which were based upon very limited material compared with what is now available, the Dinosaurs were very generally regarded as an order. Various characters were assigned to the group by von Meyer, who applied to it the term *Pachypoda*; by Owen, who subsequently gave the name *Dinosauria*, now in general use; and also by Huxley, who more recently proposed the name *Ornithoscelida*, and who first appreciated the great importance of the group, and the close relation it bears to birds. The researches of Leidy and Cope in this country, and Hulke, Seeley, and others in Europe, have likewise added much to our knowledge of the subject.

An examination of any considerable portion of the Dinosaurian remains now known will make it evident to any one familiar with reptiles, recent or extinct, that this group should be regarded not as an order but as a sub-class, and this rank is given it in the present communication. The great number of subordinate divisions in the group, and the remarkable diversity among those already discovered indicate that many new forms will yet be found. Even among those now known, there is a much greater difference in size and in osseous structure than in any other sub-class of vertebrates, with the single exception of the placental Mammals. Compared with the Marsupials, living and extinct, the *Dinosauria* show an equal diversity of structure, and variations in size from by far the largest land animals known—fifty or sixty feet long, down to some of the smallest, a few inches only in length.

According to present evidence the Dinosaurs were confined entirely to the Mesozoic age. They were abundant in the Triassic, culminated in the Jurassic, and continued in diminishing numbers to the end of the Cretaceous period, when they became extinct. The great variety of forms that flourished in the Triassic render it more than probable that some members of the group existed in the Permian period, and their remains may be brought to light at any time.

The Triassic Dinosaurs, although so very numerous, are known to-day mainly from footprints and fragmentary osseous remains. Not more than half-a-dozen skeletons, at all complete, have been secured from deposits of this period; hence, many of the remains described cannot at present be referred to their appropriate divisions in the group.

From the Jurassic period, however, during which Dinosaurian reptiles reached their zenith in size and numbers, representatives of no less than four well-marked orders are now so well known that different families and genera can be very accurately determined, and almost the entire osseous structure of typical examples, at least, be made out with certainty. The main difficulty at present with the Jurassic Dinosaurs is in ascertaining the affinities of the diminutive forms which appear to approach birds so closely. These forms were not rare, but their remains hitherto found are mostly fragmentary, and can with difficulty be distinguished from those of birds, which occur in the same beds. Future discoveries will, without doubt, throw much light upon this point.

Comparatively little is yet known of Cretaceous Dino-

[1] By Prof. O. C. Marsh. Read before the National Academy of Sciences, at the Philadelphia meeting, November 14, 1881. Communicated by the Author.

saurs, although many have been described from incomplete specimens. All of these appear to have been of large size, but much inferior in this respect to the gigantic forms of the previous period. The remains best preserved show that, before extinction, some members of the group became quite highly specialised.

Regarding the Dinosaurs as a sub-class of the REPTILIA, the forms best known at present may be classified as follows:—

SUB-CLASS DINOSAURIA

Premaxillary bones separate; upper and lower temporal arches; rami of lower jaw united in front by cartilage only; no teeth on palate. Neural arches of vertebræ united to centra by suture; cervical vertebræ numerous; sacral vertebræ co-ossified. Cervical ribs united to vertebræ by suture or ankylosis; thoracic ribs double-headed. Pelvic bones separate from each other, and from sacrum; ilium prolonged in front of acetabulum; acetabulum formed in part by pubis; ischia meet distally on median line. Fore and hind limbs present, the latter ambulatory and larger than those in front; head of femur at right angles to condyles; tibia with procnemial crest; fibula complete. First row of tarsals composed of astragalus and calcaneum only, which together form the upper portion of ankle joint.

(1.) Order SAUROPODA (Lizard foot).—Herbivorous.

Feet plantigrade, ungulate; five digits in manus and pes; second row of carpals and tarsals unossified. Pubes projecting in front, and united distally by cartilage; no post-pubis. Precaudal vertebræ hollow. Fore and hind limbs nearly equal; limb bones solid. Sternal bones parial. Premaxillaries with teeth.

(1) Family *Atlantosauridæ*. Anterior vertebræ opisthocœlian. Ischia directed downward, with extremities meeting on median line.

Genera *Atlantosaurus*, *Apatosaurus*, *Brontosaurus*, *Diplodocus*, ? *Camarasaurus* (*Amphicœlias*), ? *Dystrophæus*.

(2) Family *Morosauridæ*. Anterior vertebræ opisthocœlian. Ischia directed backward, with sides meeting on median line.

Genus *Morosaurus*.

European forms of this order: *Bothriospondylus*, *Cetiosaurus*, *Chondrosteosaurus*, *Eucamerotus*, *Ornithopsis*, *Pelorosaurus*.

(2.) Order STEGOSAURIA (Plated lizard).—Herbivorous.

Feet plantigrade, ungulate; five digits in manus and pes; second row of carpals unossified. Pubes projecting free in front; post-pubis present. Fore limbs very small; locomotion mainly on hind limbs. Vertebræ and limb bones solid. Osseous dermal armor.

(1) Family *Stegosauridæ*. Vertebræ biconcave. Neural canal in sacrum expanded into large chamber; ischia directed backward, with sides meeting on median line. Astragalus co-ossified with tibia; metapodials very short.

Genera *Stegosaurus* (*Hypsirhophus*), *Diracodon*, and in Europe *Omosaurus*, Owen.

(2) Family *Scelidosauridæ*. Astragalus not co-ossified with tibia; metatarsals elongated; four functional digits in pes. Known forms all European.

Genera *Scelidosaurus*, *Acanthopholis*, *Cratæomus*, *Hylæosaurus*, *Polacanthus*.

(3.) Order ORNITHOPODA (Bird foot).—Herbivorous.

Feet digitigrade, five functional digits in manus and three in pes. Pubes projecting free in front; post-pubis present. Vertebræ solid. Fore limbs small; limb bones hollow. Premaxillaries edentulous in front.

(1) Family *Camptonotidæ*. Clavicles wanting; post-pubis complete.

Genera *Camptonotus*, *Laosaurus*, *Nanosaurus*, and in Europe *Hypsilophodon*.

(2) Family *Iguanodontidæ*. Clavicles present; post-pubis incomplete. Premaxillaries edentulous. Known forms all European.

Genera *Iguanodon*, *Vectisaurus*.

(3) Family *Hadrosauridæ*. Teeth in several rows, forming with use a tesselated grinding surface. Anterior vertebræ opisthocœlian.

Genera *Hadrosaurus*, ? *Agathaumas*, *Cionodon*.

(4.) Order THEROPODA (Beast foot).—Carnivorous.

Feet digitigrade: digits with prehensile claws. Pubes projecting downward, and co-ossified distally. Vertebræ more or less cavernous. Fore limbs very small; limb bones hollow. Premaxillaries with teeth.

(1) Family *Megalosauridæ*. Vertebræ biconcave. Pubes slender, and united distally. Astragalus with ascending process. Five digits in manus and four in pes.

Genera *Megalosaurus* (*Poikilopleuron*), from Europe. *Allosaurus*, *Cœlosaurus*, *Creosaurus*, *Dryptosaurus* (*Lælaps*).

(2) Family *Zanclodontidæ*. Vertebræ biconcave. Pubes broad elongate plates, with anterior margins united. Astragalus without ascending process; five digits in manus and pes. Known forms European.

Genera *Zanclodon*, ? *Teratosaurus*.

(3) Family *Amphisauridæ*. Vertebræ biconcave. Pubes rod-like; five digits in manus and three in pes.

Genera *Amphisaurus* (*Megadactylus*), ? *Bathygnathus*, ? *Clepsysaurus*; and in Europe, *Palæosaurus*, *Thecodontosaurus*.

(4) Family *Labrosauridæ*. Anterior vertebræ strongly opisthocœlian, and cavernous. Metatarsals much elongated. Pubes slender, with anterior margins united.

Genus *Labrosaurus*.

Sub-Order CŒLURIA (hollow tail).

(5) Family *Cœluridæ*. Bones of skeleton pneumatic or hollow. Anterior cervical vertebræ opisthocœlian, remainder bi-concave. Metatarsals very long and slender.

Genus *Cœlurus*.

Sub-Order COMPSOGNATHA.

(6) Family *Compsognathidæ*. Anterior vertebræ opisthocœlian. Three functional digits in manus and pes. Ischia with long symphysis on median line. Only known specimen European.

Genus *Compsognathus*.

DINOSAURIA?

(5.) Order HALLOPODA (leaping foot).—Carnivorous?

Feet digitigrade, unguiculate; three digits in pes; metatarsals greatly elongated; calcaneum much produced backward. Fore limbs very small. Vertebræ and limb bones hollow. Vertebræ biconcave.

Family *Hallopodidæ*.

Genus *Hallopus*.

The five orders defined above, which I had previously established for the reception of the American Jurassic Dinosaurs, appear to be all natural groups, well marked in general from each other. The European Dinosaurs from deposits of corresponding age fall readily into the same divisions, and, in some cases, admirably supplement the series indicated by the American forms. The more important remains from other formations in this country and in Europe, so far as their characters have been made out, may likewise be referred with tolerable certainty to the same orders.

The three orders of Herbivorous Dinosaurs, although widely different in their typical forms, show, as might be expected, indications of approximation in some of their aberrant genera. The *Sauropoda*, for example, with *Atlantosaurus* and *Brontosaurus*, of gigantic size, for their most characteristic members, have in *Morosaurus* a branch leading toward the *Stegosauria*. The latter order, likewise, although its type genus is in many respects the most strongly marked division of the Dinosaurs, has its

Scelidosaurus, a form with some features pointing strongly towards the *Ornithopoda*.

The Carnivorous *Dinosauria* now best known may all be placed at present in a single order, and this is widely separated from those that include the herbivorous forms. The two sub-orders defined include very aberrant forms, which show many points of resemblance to Mesozoic birds. Among the more fragmentary remains belonging in this order, but not included in the present classification, this resemblance appears to be carried much farther.

The order *Hallopoda*, which I have here referred to the *Dinosauria*, with doubt, differs from all the known members of that group in having the hind feet specially adapted for leaping, the metatarsals being half as long as the tibia, and the calcaneum produced far backward. This difference in the tarsus, however, is not greater than may be found in a single order of Mammals, and is no more than might be expected in a sub-class of Reptiles.

Among the families included in the present classification, I have retained three named by Huxley (*Scelidosauridæ*, *Iguanodontidæ*, and *Megalosauridæ*),[1] although their limits as here defined are somewhat different from those first given. The sub-order *Compsognatha*, also, was established by that author in the same memoir, which contains all the more important facts then known in regard to the *Dinosauria*. With the exception of the *Hadrosauridæ*, named by Cope, the other families above described were established by the writer.

The *Amphisauridæ* and the *Zanclodontidæ*, the most generalised families of the *Dinosauria*, are only known from the Trias. The genus *Dystrophæus*, referred provisionally to the *Sauropoda*, is likewise from deposits of that age. The typical genera, however, of all the orders and sub-orders are Jurassic forms, and on these especially the present classification is based. The *Hadrosauridæ* are the only family confined to the Cretaceous. Above this formation, there appears to be at present no satisfactory evidence of the existence of any *Dinosauria*.

[1] Quarterly Journal Geological Society of London, vol. xxvi. p. 34. 1870.

THE TAY AND THE FORTH BRIDGES

THE reconstruction of the Tay Bridge (if it really go on) by Mr. W. H. Barlow and the re-designing of the Forth Bridge by Mr. John Fowler and Mr. B. Baker will undoubtedly mark a new point of departure in the practice of British engineers. With the advent of railways there arose a generation of engineers who for some inexplicable reason ignored the traditions of their predecessors and gave no thought to wind pressure. Previous to this the question was always considered of vital importance by constructors. For example, Tredgold, writing some sixty years ago about roofs over building slips, directed special attention to the fact that such structures were "much exposed to be racked and strained by high winds," and recommended certain proportions, based upon the assumption of the actual weight of the roof being 16 lbs. per square foot, and the pressure of the wind 40 lbs. per foot. He thus clearly warned engineers that in some instances the pressure of the wind and not the load governs the strength of the structure. Nevertheless so completely have British engineers ignored this condition that it may safely be said at least three-fourths of the railway bridges in Great Britain and Ireland have no lateral bracing or provision of any kind to enable them to resist wind pressure. Even metallic arched bridges, which from their form must, in the absence of cross bracing, be necessarily in a state of more or less unstable equilibrium, form no exception to the rule. At Richmond, for instance, and at Kingston also, there are cast-iron arches about 100 feet in span, the lateral stability of which is dependent solely upon the 8 inches or 10 inches wide flanges of the arched ribs. There is no lateral bracing nor are there any iron cross-girders to bind the arched ribs together, and the lateral stiffness of a 10-inch flange over a span of 100 feet is more easily imagined than calculated. Within a few hundred yards of the Richmond Bridge is an anemometer which, according to the official returns, has not infrequently recorded a pressure of 27 lbs. per square foot, but it is hardly necessary to say that no wind pressure even approximating to that amount could ever have taken effect on the bridge.

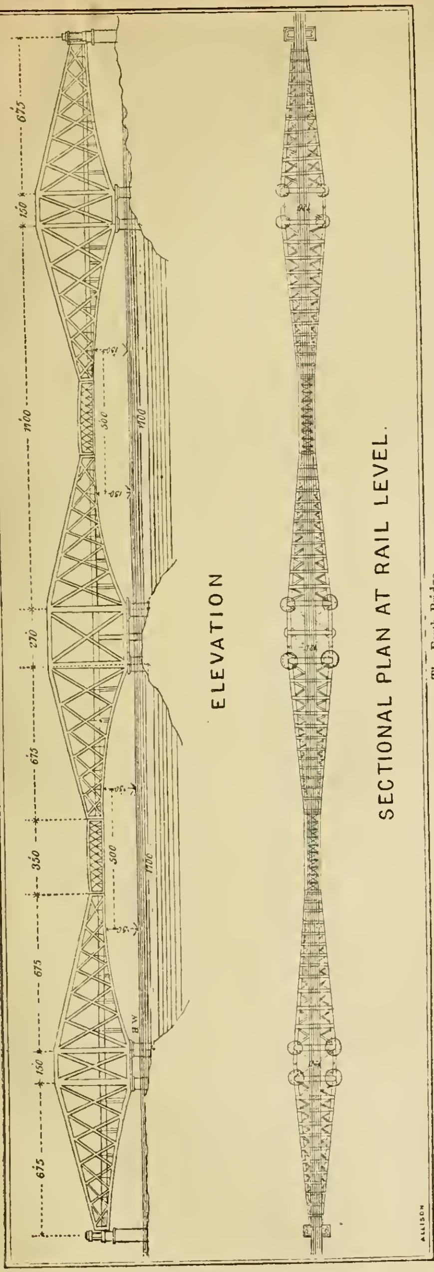
Since the fall of the Tay Bridge the principles and practice of Telford's day have been reverted to by British engineers, and the question of wind pressure has been most influential in determining the design and proportions of the new Tay and the proposed Forth Bridges.

In the original Tay Bridge the type of pier foundation finally developed was, it may be remembered, a single cylinder of 31 feet diameter. This was satisfactory enough as regards vertical pressure, but in the new design it was lateral and not vertical pressure which governed the form of the pier's foundation, and the latter will consist not of a single 31 feet cylinder but of two 23 feet cylinders spread 32 feet apart centre to centre, and affording correspondingly increased lateral stability. Similarly, as regards the metallic piers resting on these foundations: originally these consisted of a group of cast iron columns, and as regards vertical pressure nothing could be better, for, as we have recently ascertained by tests, a hollow cast-iron column of ordinary proportions will carry more load than either a wrought iron or a steel tube of equal weight. When the bending action of the wind upon a bridge pier is taken into consideration, however, the steady vertical pressure due to the load becomes of comparatively little moment, and Mr. Barlow has very properly adopted wrought iron for the piers of the new Tay Bridge, and the Board of Trade have with no less propriety intimated, in their recent "Memorandum of Requirements," that piers made up of a group of small cast-iron columns will no longer be passed by the inspecting officers.

The superstructure of the new Tay Bridge, no less than the piers, affords evidence of the provision which it is now thought necessary to make against the consequences of high wind pressures. Thus Mr. Barlow has provided three lines of defence against a train being hurled into the Tay, firstly, a guard balk of considerable height outside each rail; secondly, a ballasted floor of sufficient strength to hold up a derailed locomotive at any point; and thirdly, a strong iron parapet. Most of these provisions will in all probability be insisted upon by the Board of Trade in future railway bridges.

Turning now to the gigantic Forth Bridge, the influence of wind pressure in determining the design is beyond all precedent. The assumed lateral pressure of the wind upon the 1700 feet span girder is in fact no less than 50 per cent. greater than the maximum rolling load, so that were it not for the influence of gravity on the mass of the bridge, the required strength would be greater laterally than vertically to the extent of one-half. The weight of steel in the 1700 feet girder is, however, so considerable, that the stresses both for rolling load and wind pressure are relatively less than in smaller bridges.

The original design for the Forth Bridge by Sir Thomas Bouch was, it will be remembered, on the suspension principle. Except as regards the enormous drop in the suspension chains and the consequent unprecedented height of the piers, there was little to distinguish the proposed structure from an ordinary suspension bridge with stiffening girder, and without the inclined stays characteristic of American suspension bridges. During the past forty years the suspension principle has been universally rejected by engineers of all countries as unsuitable to the conditions of high-speed railway traffic, and the only reason for introducing it in the case of the Forth Bridge was the assumption that no other plan was commercially



The Forth Bridge.

attainable. It caused no little surprise therefore, and not a few expressions of incredulity, when Messrs. Fowler and Baker announced that the span of 1700 feet was no reason at all for departing from the old and well-tested principle of girder construction, but that on the contrary a girder bridge of proper design would be not only infinitely stiffer, but also considerably cheaper, than a structure on the suspension principle. This conclusion was however confirmed by Mr. W. H. Barlow and Mr. T. E. Harrison after careful independent investigation, and a design was finally agreed upon by all the engineers and accepted by the four railway companies finding the funds for its construction.

The Forth Bridge as intended to be constructed may be briefly described as a continuous steel girder bridge, of varying depth and with fixed points of contrary flexure. In several essential points it is analogous to the well-known continuous tubular girder bridge across the Menai Straits, as in both cases the continuous girder traverses two main spans and two end spans of about half the width of the former. In the Forth Bridge, however, the main spans are 1700 feet, and the end spans 675 feet, whilst in the Britannia Bridge the respective dimensions are but 460 feet and 230 feet. It is hardly necessary to say, therefore, that though the principle is the same the proportions and general details of the two structures present no points of resemblance.

The continuous girders of the Forth Bridge are 340 feet, or one-fifth of the span, in depth at the piers, and only 45 feet deep at the centre of the 1700 feet span. In ordinary continuous girders the points of contrary flexure are situated about one-fifth of the span from the piers, but in the Forth Bridge they are fixed at the most economical distance, which was found on investigation to be about two-fifths. Every continuous girder may, for purpose of calculation, be regarded as made up of a central girder supported by two cantilevers. In ordinary cases the central girder will have an effective span about equal to the total span $\div \sqrt{3}$. If the Forth Bridge were an ordinary continuous girder the effective span of the central girder would thus be about 982 feet, but as a matter of fact it will be made 350 feet, and it is to this deviation from the ordinary proportions that the economy of the design is largely due. By keeping the central girder of moderate span, or in other words by removing the points of contrary flexure farther from the piers, the central portion of the girder is lightened, the bending moment correspondingly reduced, and the mass of metal is concentrated near the piers, where it acts with the least leverage. Thus the lower member of the great girder, where it springs from the masonry piers at a height of 20 feet above high water, is a steel tube 12 feet diameter and about 2 inches thick, whilst at the centre of the span, where the bottom member has been cambered upwards to a height of 150 feet for navigation purposes, it is of ordinary trough section, about 3 feet in width.

On plan as well as in elevation the Forth Bridge is a continuous girder of varying depth. To resist high wind pressures the tubular lower members are spaced 120 feet apart, centre to centre at the piers, whereas the trough lower members of the central girder are spaced but 27 feet apart. By varying the effective depth of the girder both on plan and elevation a great saving is effected in the bracing, as the shearing stresses are to a large extent taken up by the main members of the girder. In a bow-string girder the bracing is similarly lightened by the arching of the top member. There are other sources of economy in the proposed design which we have not space to refer to at present.

It is intended, we understand, to give such proportions to the several members of the structure that under the combined stresses resulting from the maximum rolling load and a wind pressure of 56 lbs. per square foot, the stress per square inch will in no case exceed one-

fourth of the ultimate strength of the steel used in construction. The steel used in compression will be considerably stronger and harder than the more ductile material used for the parts in tension.

Facility of erection has necessarily been one of the most important governing elements in the design of the Forth Bridge. With 200 feet depth of water, scaffolding is of course out of the question, and the only practicable way of erecting the great girders is by commencing the work at each pier and adding successive bays of struts, ties, and bracing on either side, until the whole structure is complete. This mode of erection, technically known as "erection by overhang," is that which has been successfully adopted in the two largest railway bridges yet constructed, namely, the St. Louis Bridge across the Mississippi, of 525 feet span, and the Douro Bridge, of the same span, near Lisbon. The great advantage and security of erection by overhang in a case like the Forth Bridge is that every piece of the work is finished and securely braced against storms before another length is commenced. When the bridge is partially finished it will at the distance present much the appearance of three huge birds perched with outspread wings on as many rocks. The distance between the tips of the wings will be represented by that between the ends of the cantilevers, or say, 1500 feet. It might be thought that this would be a critical stage of the erection, but it is not so, as the work is so designed that if a hurricane of 56 lbs. per square foot were to strike one wing whilst the other remained becalmed the cantilevers would not spin round like a weathercock, but remain perfectly stable and secure.

We understand that the Board of Trade have signified their approval of the design and of the provisions made by the engineers as regards strains and wind pressures.

NOTES

THE last work of the late Mr. H. C. Watson on the distribution of British plants was his "Topographical Botany," published in 1873-4, in which he traced the dispersion of each species through the 112 vice-counties of Britain which he adopted. Of this book only 100 copies were printed for private circulation, and these were all given away by the author immediately. Since its issue a large amount of new material has been accumulated, principally through the exertions of the members of the Botanical Record Club, and at the time of his death, last autumn, Mr. Watson was engaged in the preparation of a new edition. This he did not live to complete as regards its prefatory and explanatory portions, but he had kept an interleaved copy in which he regularly entered up every record of any plant in a new district that was brought to his notice. At his own special request this was deposited with his herbarium at Kew, and from this it is now proposed to prepare a second edition of the book, which Mr. Quaritch has undertaken to publish, and Mr. J. G. Baker, of the Royal Gardens, and the Rev. W. W. Newbould to make ready for the press.
